## Dead Reckoning

Jason N. Bruck

Department of Integrative Biology, Oklahoma  
State University, Stillwater, OK, USA

*Dead Reckoning*: An animal's inability to see, smell, echolocate, or feel its way around an environment does not necessarily preclude successful navigation. Instead an animal may use a mechanism called dead reckoning to navigate. A navigator's phrase, *dead reckoning*, is also synonymous with *path integration*, meaning the organism uses cumulative information about its distance and direction to find a way back to the origin of the journey (Shettleworth 2010). Dead reckoning, as described by Gallistel (1990) is defined as an egocentric mode of navigation (see ► [Egocentric Frame](#)) that is based on the individual localizing with respect to itself. Egocentric navigation explains how a human can move around an unfamiliar darkened room with some limited success, capable of returning to a starting point after fumbling around the space for a few minutes. In these instances, an organism may use self-referential vestibular cues (Etienne et al. 1986), sensory input from leg mechanoreceptors (Seyfarth and Barth 1972), or external visual flow patterns that change with respect to the individuals' speed and heading (Saint Paul 1982; Ugolini 1987). Self-referential cues are best exemplified by the use of vestibular senses by nocturnal mammals [in gerbils: (Mittelstaedt and Mittelstaedt 1982); in hamsters: (Georgakopoulos and Etienne 1994)] to identify distance and direction. External cue usage in dead reckoning is also seen in diurnal species like bees (Ugolini 1987) and geese (Saint Paul 1982) and relies on patterns of visual flow to determine displacement. Dead reckoning as a form of egocentric navigation is in contrast to allocentric or geocentric modes of navigation that emphasize the environment's unique features and the animal's localization within an external frame of reference. External cue usage in dead reckoning differs from external cue usage in allocentric or geocentric modes because features of

the environment are not attended to in the egocentric frame. It is helpful to picture a high-speed camera over a busy city street at night with cars moving so fast that all one sees is the blur of the lights. Features of objects are indistinguishable, but an individual can identify distance and direction traveled simply by the flow of light.

Shettleworth (2010) characterized egocentric navigation as relying on a short-term memory system, processing information related to internal cues collected on a current "expedition," and reset upon the completion of that particular track and the beginning of another. However, care must be made to not see egocentric navigation as precisely synonymous with dead reckoning, as vestibular senses can mediate the route-style navigation typified by tunneling species (Bruck et al. 2017). Theoretically, a nocturnal organism using dead reckoning can wander about in the absence of any external cues but still be able to go from any point on a trip and return to the starting place (Fig. 1). In contrast, route-navigation mediated by egocentric cues does not necessarily see the subject returning to a starting point.

So far, scientists have identified evidence for vertebrate dead reckoning in golden hamsters (Georgakopoulos and Etienne 1994), gerbils (Mittelstaedt and Mittelstaedt 1982), rats (Dudchenko and Bruce 2005; Shettleworth and Sutton 2005; Watson 1907), pigeons (Sutton and Shettleworth 2005), geese (Saint Paul 1982), and possibly voles (Eilam et al. 2003). Invertebrate examples include desert ants (Wehner and Srinivasan 1981), wasps (Ugolini 1987), and bees (Dyer 1996) to name a few.

By no means is dead reckoning a perfect system. In most cases, this is not a true mathematical integration (as the term path integration might suggest); therefore, errors tend to accumulate over time. This makes long-distance movement using dead reckoning dangerous. Some animals have mechanisms to adjust for the problem. For instance, desert ants use a wider spiraling search pattern upon return to the nest after longer journeys (Wehner and Srinivasan 1981). These wider search loops are possibly a consequence of less certainty with the exact location of the nest entrance. Another disadvantage of dead reckoning

**Dead Reckoning, Fig. 1** Foraging with dead reckoning. An organism's foraging journey in a featureless environment with the solid line representing the outgoing path in search of food and the dashed line representing the fairly direct successful return trip to the home nest mediated by dead reckoning. (Adapted from Wehner (2003) with permission from the author)

is that it usually does not compensate for slow to moderate course alterations that are uninitiated or undetected by the organism. Such events may result from wind, shifts in sand, or experimenter movement (Mittelstaedt and Mittelstaedt 1982). Dead reckoning is also subject to limitations in memory, so far as the process is cognitive. As distance travelled increases, the probability of getting lost also increases due to a higher likelihood of the animal forgetting. Without using external visual cues, there is no way for an animal to consolidate referential units of memory or to correct for errors inherent to path integration.

Experimentally, egocentric navigation can be studied using two broad methodologies. One method incorporates open field designs in what is considered a test of true dead reckoning. Here an animal's ability to return to a starting point is tested in the absence of allocentric and geocentric cues. Often this can involve using rotating platforms that turn too slowly to be perceived by the

subject's vestibular senses or experimenter translocation of animals' part way through their journey to see if errors are reflective of the distance they were moved (see Shettleworth 2010 for review of studies). One can also use mazes to study egocentric route navigation (Benhamou 1997; Bruck et al. 2017; Shettleworth 2010). In these cases, again, it is not dead reckoning that is necessarily assessed (because the animals do not necessarily travel to a location and then return to start), but rather sensory mechanisms used in dead reckoning, integrated with cognitive map formation, that are of interest. This is not to say that route-based egocentric navigation does not inform our understanding of dead reckoning, as one may be studying many of the same underlying perceptual systems an organism uses in dead reckoning.

In considering the evolution and neurological basis of egocentric navigation, it is interesting to note that impairment of the interpeduncular nucleus affects both landmark navigation and egocentric navigation but not beacon navigation (Clark and Taube 2009). Both beacon and landmark navigation are examples of allocentric navigation (Shettleworth 2010), yet it seems the landmark and egocentric modes may share brain structures. This might be explained by the associative nature of beacon navigation (navigate to perceptible target) and the integrative natures of egocentric and landmark navigation (where multiple cues are needed to orient a navigator).

## Dear Enemy Effect

James P. Tumulty

Department of Ecology, Evolution, and Behavior,  
University of Minnesota – Twin Cities, St. Paul,  
MN, USA

## Synonyms

Dear enemy phenomenon; Neighbor-stranger discrimination

## Definition

Reduced aggression between established territorial neighbors relative to strangers

## Introduction

Territorial animals defend resources needed for survival and reproduction. Animals advertise their ownership of territories through conspicuous signals; birds and frogs vocalize, mammals and salamanders scent mark, lizards display colorful patterns, and fiddler crabs wave their oversized claws in the air. If advertisement is not enough, animals may have to fight off intruders to maintain territory ownership. However, animal fights are relatively rare, even when territories are spatially clumped resulting in frequent interactions between neighbors. Once territories are established, individuals in neighboring territories typically respect territorial boundaries and withhold aggression from their neighbors. This makes sense because aggression can be costly, and if a neighbor already has a territory, they might not represent a threat to a territory holder. However, territory holders will often maintain a readiness to be aggressive toward unfamiliar individuals,

showing more aggression to strangers than to familiar neighbors. This phenomenon of reduced aggression between established neighbors relative to strangers is called the “dear enemy effect” and is thought to allow animals to minimize the costs of territory defense (Wilson 1975).

The term “dear enemy” originates with observations made by James Fisher (1954) that songbirds often establish territories in clusters and have relationships with their neighbors that are not strictly competitive. Fisher wrote that “the effect of the holding of territory . . . is to create “neighbourhoods” of individuals which are masters of their own definite and limited property, but which are bound firmly, and *socially*, to their next door neighbours by what in human terms would be described as a dear enemy or rival friend situation.” Much of the early research on the dear enemy effect was conducted on territorial songbirds, which often respond less aggressively to the familiar songs of their neighbors than they do to the unfamiliar songs of strangers. Since this early work on birds, the dear enemy effect has been documented in many different taxonomic groups, including insects, crustaceans, fish, amphibians, reptiles, and mammals.

### Adaptive Significance

Individuals must balance the benefits and costs of defending a territory. The primary benefit of holding a territory is the exclusive access to resources that may be limited in the environment. Defended resources may include feeding grounds, areas to advertise to and court mates, reproductive resources such as oviposition or nesting sites, and shelter. However, aggressively defending these resources from conspecifics incurs costs, such as energy spent on aggressive encounters, missed opportunities to feed or mate, risk of injury during fights, and decreased vigilance against predators. We should generally expect that evolution has equipped territorial animals with decision rules that allow them to maximize the difference between the benefits and costs of territory defense. The dear enemy effect is the product of such a decision rule, but why, exactly, is it adaptive to treat neighbors and strangers differently?

There are two hypotheses to explain the adaptive value of behaviorally discriminating between neighbors and strangers. The “relative threat” hypothesis (Getty 1987) rests on the assumption that strangers pose a greater threat to territory holders than do neighbors. The idea is that strangers are likely to be non-territorial “floaters” that are looking to establish a territory by taking over an existing territory or inserting themselves into a network of territories. Territory holders thus risk either losing their territory to a stranger or gaining an additional competitor if a stranger settles nearby. In contrast, a neighbor already has a territory of its own; neighbors may compete for mates or food but they do not pose a threat to territory ownership. By maintaining high levels of aggression toward strangers and tolerating nearby neighbors, territorial animals can both reap the benefits of possessing a limited resource and minimize the costs of defending that resource. Along a different line of reasoning, Ydenberg et al. (1988) proposed that a dear enemy effect functions to minimize the costs of escalated conflicts between neighbors and is possible because familiar neighbors have established dominance relationships. This “familiarity” hypothesis rests on the assumption that the relationship between neighbors is established through repeated conflicts, and once dominance relationships are established, individuals are less likely to make role mistakes in future conflicts. Strangers, however, do not have established relationships and need to escalate conflicts to determine dominance roles. Thus, interactions are more likely to escalate to higher levels of aggression between unfamiliar individuals than they are between familiar neighbors.

While the “relative threat” and “familiarity” hypotheses are not mutually exclusive, they do make different predictions about when a dear enemy effect should be adaptive. The “familiarity” hypothesis predicts a dear enemy effect any time neighbors can become familiar with each other. The “relative threat” hypothesis predicts a dear enemy effect only for situations in which strangers pose a greater threat than neighbors, regardless of how familiar neighbors may be. Temeles (1994) reviewed studies of the dear enemy effect and found that the results are

generally consistent with the “relative threat” hypothesis. Among birds, the dear enemy effect is typically observed in species that defend multi-purpose breeding territories, where neighbors may compete for mates or food, but strangers threaten complete territory takeover. It is often not observed in species that defend single-purpose feeding territories or nest sites, where neighbors and strangers both represent equivalent threats to food or nesting resources and are treated the same by territory holders. Some of the best evidence for the relative threat hypothesis actually comes from situations in which neighbors are more of a threat than strangers, and territory holders correspondingly direct more aggression toward neighbors (Temeles 1994).

## Neighbor Recognition

Many researchers are interested in the dear enemy effect because it allows them to study social recognition. Learning to recognize familiar neighbors allows territorial animals to direct aggression toward strangers, producing a dear enemy effect. However, the dear enemy effect and neighbor recognition are not synonymous. A dear enemy effect could be produced in the absence of neighbor recognition. For example, if individuals that do not possess territories behave differently than individuals that have territories, the behavioral cues of non-territorial strangers could be perceived as more threatening and elicit stronger aggressive responses from territory holders. On the other hand, one could observe neighbor recognition in the absence of a dear enemy effect if, for example, territory holders are more aggressive toward neighbors than strangers. Finally, a lack of observed behavioral discrimination between neighbors and strangers cannot rule out the possibility that a territory holder recognizes a neighbor but simply treats neighbors and strangers with equal levels of aggression.

Nevertheless, many studies of the dear enemy effect are also tests of neighbor recognition. The pioneering work on neighbor recognition was conducted on songbirds (Stoddard 1996). Territorial male songbirds often respond more

aggressively to the songs of strangers than the songs of neighbors played from the direction of the neighbor’s territory, showing that they learn to recognize the vocalizations of their neighbors. Further, territory holders often respond more aggressively to their neighbor’s songs played from an unfamiliar location than from their neighbor’s territory, suggesting that these birds have the capacity to recognize multiple individual neighbors based on vocalizations and location (Stoddard 1996). Similar results have been obtained in territorial bullfrogs (Bee et al. 2016) and damselfish (Myberg and Riggio 1985). Some studies have demonstrated individual recognition of neighbors independent of location. For example, though male bullfrogs are more aggressive to the vocalizations of a neighbor played from an unfamiliar location, they still show less aggression to neighbors in an unfamiliar location than to strangers in an unfamiliar location (Bee and Gerhardt 2002). Another experimental approach uses a neutral arena; Husak and Fox (2003) showed that male collared lizards are less aggressive toward familiar neighbors in the field and in staged interactions in a neutral arena, demonstrating individual recognition independent of location.

The dear enemy effect has allowed researchers to investigate a variety of perceptual and learning mechanisms that allow animals to recognize familiar individuals. In order to recognize familiar neighbors, territorial animals must be able to perceive the differences in signals produced by different individuals. Experiments in sparrows and bullfrogs have shown that territorial individuals can perceive individual differences in frequency of vocalizations, allowing them to recognize the vocalizations of familiar neighbors (Brooks and Falls 1975; Bee et al. 2016). Research on the dear enemy effect has also revealed that territorial animals can learn to recognize familiar neighbors through habituation, a common form of learning in which animals gradually decrease response to a stimulus with repeated exposure to that stimulus. Neighbors may initially be aggressive with each other during territory formation, but their aggression gradually habituates as territory boundaries are established. Because habituation is specific to a certain stimulus, habituation to the signal

properties of a familiar neighbor can allow a territory holder to recognize a particular individual by those signal properties (Bee et al. 2016). Other forms of learning are certainly involved in neighbor recognition in some species. For example, song sparrows have dear enemy relationships with their neighbors, and neighbors interact with each other by singing songs that they share in common (Beecher et al. 1996).

## Conclusions

The dear enemy effect occurs when territorial animals direct less aggression toward established territorial neighbors than toward strangers. This is a common phenomenon among territorial animals and has been documented in many different taxonomic groups. By withholding aggression from neighbors, animals can minimize the costs of territory defense. The general consensus of research on the dear enemy effect is that animals are more aggressive to strangers because strangers pose a greater threat to territory holders than do neighbors. The dear enemy effect is often made possible by the ability to recognize familiar neighbors and has allowed researchers to understand some of the perceptual and learning mechanisms that underlie this common form of social recognition.

| Chimpanzees      | Very rare  | Multimodal cues  | Testing for life signs (?)   |

D

the fact that they have been burying their dead as early as 120 Kya; however, they are not the only animal to do this. In reality, other species in the animal kingdom engage in “burying behavior,” while the underlying causes vary substantially (see Table 1). In humans, the concept of death develops from ages 3 to 10 with subcomponents being grasped at different ages. In our lineage, burials came from the realization something had to be done with the corpse, as suggested from their deliberate rather than instinctive/accidental/incidental nature in nonhuman animals. Corpses can be a source of critical information; they can signal predation events, food resource, or pathogen hazard. In this regard, a constellation of behaviors can ensue around dead conspecifics and their sensory cues; fishes/rodents avoid corpses of conspecifics due to the presence of death-associated odors, corvids alarm call/gather around their dead, while elephants investigate the bodies/bones of dead conspecifics, and nonhuman primates carry dead infants. By looking at our closest living relatives and further down the evolutionary lines, we can begin to glimpse what came before elaborate ways of treating/conceiving the dead and understand the evolutionary pressures behind it.

**Animacy Detection Malfunction**

Upon detection, corpses present a conundrum; having both inanimate and animate attributes they are uncanny, defying expectations and provoking confusion among the living. Like *agents*, they exhibit *static cues* to *animacy* (shape and texture), but like *objects* they lack *dynamic cues* to *animacy* (self-propelled motion and contingency). Gonçalves and Biro (2018) proposed the

term *animacy detection malfunction*, understood as the conflicting cognitive processes brought about by such perceptual mismatches causing violations of expectation when a corpse is detected. Hypothetically, such conflict stems from the activations of two different cognitive systems in the brain, one dedicated towards agency detection and another for object detection. This is illustrated by many accounts of social nonhuman animals displaying approach/avoidance and exploratory/fearful responses when encountering a corpse, in some cases a conspecific which they recognize and interacted with throughout their lives.

**Thanatological Interactions**

Thanatological responses (behaviors towards the dead) are often observed in many animal species, but only few are interpreted as epimeletic (helping) behaviors (Gonçalves and Biro 2018). Among mammals, and to some extent birds, they include mothers stationing around, physically interacting, and/or carrying their dead offspring. The main reason lies in phylogenetically ancient caregiving mechanisms mediated by oxytocin and its homologues continuing to function even after the offspring has died. In vertebrates, these hormones originally served a function for “basic” reproductive behavior (vocalizing, courtship behavior, nest building) and then extended to more “advanced” reproductive behavior (pair bonding and parental care) culminating in social bond formation and maintenance (Knobloch and Grinevich 2014) (Fig. 1).

From a proximate perspective, the mother perceives her infant’s condition as unclear,

**Death, Fig. 1** Similarities of dead offspring carrying behavior. Left: a female African bush elephant (Photo credit: Anna Ritenour). Right: a female Eastern chimpanzee. (Photo credit: Charlotte Richardson)

anticipating that it will still recover, thus continuing to invest in it. From an ultimate perspective, the constant caretaking behaviors result from error management, since the fitness cost of abandoning a temporarily unresponsive infant would be higher than continuing investing for a limited period. Such deaths are followed by a transitional phase that can vary extensively depending on taxa, individual, or external factors (from hours, days to weeks or months) whereupon the mother will stay in close proximity and physically interact with the corpse (e.g., inspecting/licking, grooming). These responses decrease over time always culminating in the abandonment or loss of the corpse.

In nonhuman primates, the most common response is dead infant carrying. There are currently many hypotheses explaining not only the occurrence but also the maintenance of this behavior ranging from anatomical (handling and carriage ability), physiological/emotional (hormones and grief management), perceptual/cognitive (error management, infantile cues), to life history (parity, individual differences) and ecological factors (climate, arboreality/terrestriality) (Gonçalves and Carvalho 2019). One issue is that some are not mutually exclusive; the mother may not fully comprehend the infant's state is final, she might be guided by her postpartum hormones, holding the infant may act as a buffer to grief, and drier climates and easier

locomotive habitats might facilitate and prolong such responses. Nonetheless, the motivations to station around a corpse versus carrying it are the same, the primary distinction for the latter being a physical one; non-primates have dexterous limbs that permit such carriages when other vertebrates do not. Cetaceans and, to a lesser degree, elephants have also been observed carrying dead offspring (Fig. 1), the first due to buoyancy in aquatic environments and the second owing to a dexterous trunk. Other reports suggest this carrying behavior is more widespread among taxa, including wolves (using the mouth) and hippopotami (in water).

Concerning interactions towards adult conspecifics, three main behavioral responses can occur: *guarding*, *vigils*, and *visitations*. *Guarding* is expressed through alarm calling, harassment responses, and rescue attempts, whereupon the individual defends the corpse from perceived threats. *Vigils* are defined as physical proximity towards the corpse for extended periods. *Visitations* are characterized as returns to the place where death ensued or the corpse was last seen. These responses share behavioral traits with sympathetic concern and empathetic targeted helping as usually they are performed by kin or closely bonded individuals. While these behaviors are mainly found in nonhuman primates (Gonçalves and Carvalho 2019), with the aid of camera traps, they have been recorded in other close-bonded

animals such as elephants and collared peccaries (de Kort et al. 2018; Hawley et al. 2018).

Most parsimoniously, these responses reflect a limited/implicit awareness of death (agency cessation) that requires constant status updating. Emotional motivations underlying such responses are temporarily overruling more cognitive aspects of death recognition as evidenced by the responses of individuals less bonded with the dead who cease their interactions sooner than strongly bonded individuals. From an evolutionary perspective, this makes sense as with dead infants, caretaking activities directed towards other group members would be advantageous if unresponsive individuals would recover.

### Grief-Like Responses

In describing grief, Charles Darwin made a distinction between two states: *excessive grief* and *sorrow*. The former was categorized as “frantic” and “energetic,” whereas the latter was “languid” and “dull.” Because our closest primate relatives do not weep nor show the facial expressions associated with sadness, Darwin concluded grief to be a typically human response. Nevertheless, later research on depression in both humans and monkeys similarly recognized these two states as protest (active) and despair (passive) which alternated back and forth.

The study of emotions, particularly attributing grief to nonhuman animals, is a matter of ongoing debate, as many researchers place emphasis on either the unobservable nature of mental aspects of grief or the uniqueness of human grief and it being inextricably tied to the concept of death. However, considering grief is predominantly associated with behavioral and physiological changes in the individual (sleep disturbances, decreased social activity, decreased appetite, increased self-directed behaviors, stress hormone elevations), it is important to point out such changes have been documented both in humans and nonhuman primates (Gonçalves and Carvalho 2019). Moreover, research in macaques shows the neurobiological foundations in these depressive states (gene-environment interactions and

serotonin) are the same as in humans. And although the majority of behavioral reports comes from nonhuman primates, there is convergent evidence from other animals including both mammals and bird species.

### Notable Empirical Research

Necrophobic behaviors, exhibited by aversion to death scents (cadaverine/putrescine), appear to be a highly conserved response, either innate or acquired quickly through learning. These are adaptive and would have been selected in terms of predator evasion or pathogen avoidance. In experimental settings, zebra fish, lampreys, sharks, but also mice typically avoid scent from decaying conspecifics. Experiments conducted in corvids show that when detecting a dead conspecific or similar-sized heterospecific, they tend to engage in cacophonous aggregations, likely as a form of mobbing and alarm-calling behavior, and will usually avoid the places where dead conspecifics were, apparently because of predation hazard (reviewed in Gonçalves and Biro 2018).

Studies demonstrating the strong influence of caretaking in birds showed that passerines will still incubate dead chicks placed in the nest even when they exhibit clear signs of injury (Leniowski et al. 2013). Additional observations of failed nests due to predation show species of passerine parents coming back to the nests (engaging in incubation and food provisioning), again, likely due to a strong caretaking drive that is not immediately switched off after nest predation. Notably, they found this maladaptive response was impacted by chick age at death; the older the offspring, the sooner parents abandoned the nest (Henschke et al. 2016). Collective experiments from mice show that multiparous females retrieve and show more caretaking behaviors than nulliparous females and, apparently, either group does not differentiate between live and dead pups as they retrieved them suggesting, with mediation from post-parturition hormones, visual/scent cues suffice to elicit this response rather than auditory stimuli (ultrasound pup vocalizations) (Gandelman et al. 1970).

*Contra* previous claims that nonhuman primates rarely console bereaved group members, Goldsborough et al. (2020) showed that, after a captive chimpanzee mother lost her infant, group members showed high levels of reassuring behaviors the same day and increased affiliative responses towards her following the loss. These and similar studies emphasize the role of empathy in managing social relationships.

## Conclusion

There is a strong argument for some thanatological responses indicating attachment relationships and operating on the expectation the dead conspecific could recover. Seemingly maladaptive, they may, however, serve an evolutionary purpose. By engaging in the abovementioned thanatological behaviors, socially bonded animals are gathering information on the conspecific's state. Additionally, they promote a faster recategorization from living to dead and reduce costly caregiving responses, may be essential to grief management, updating ranks in the hierarchy, and accelerating the formation of new social bonds. More empirical research is needed and is currently being done targeted at these and other questions relating to animal grief and awareness of death that will be fundamental in expanding our knowledge of how animals respond towards death.

## Decision-Making

Florence Landry

Department of Anthropology, University of  
Toronto, Toronto, ON, Canada

### Definition

The process used to choose between different options.

### Introduction

Animals face multiple choices throughout a day and therefore must make decisions on a daily basis in several areas. Decisions can include choosing when to feed, when to sleep, where to go, and what path to use to reach a destination, to simply decide to continue or change the current activity. In each case, animals have to take into consideration a variety of factors, including the physiological needs of themselves and of conspecifics, as well as the characteristics of their environments such as the location of resources or the presence of predators. Since the outcome of a decision can be critical for the survival and the reproductive success of an individual, a decision-making process has evolved to determine which choice should have the priority at a particular time (McFarland 1977). In addition to this process, a collective decision-making process has also evolved within groups, where different mechanisms are involved to make decisions as a group.

### Animal Decision-Making

Decision-making is the process by which an animal makes decisions by choosing between different options. Such process includes different stages with different mechanisms involved, where choices emerge from the combined action of sensory integration, cognitive mechanisms, and decision rules. Animal decision-making process begins with the acquisition of information gained

through their senses. Information can come from different sources such as the environment in which they evolve or the inner state of an individual, which can provide information on the level of satiety or the level of fatigue. Individuals invest time and energy to collect various information and to evaluate and integrate it, via cognitive processes, to create a set of sensory data. These data allow the individual to reach an “informational state,” where all the information that is known can be taken into consideration in order to make a decision (Blumstein and Bouskila 1996). Decisions are then made based on this informational state using decision rules and strategies, which result in behavioral actions that change or maintain the state of the decision-maker. The consequences of a decision can then be re-evaluated to consolidate the experience into a memory that can influence future decision-making (Owen et al. 2017).

The informational state used to make a decision is not a binary state where an individual is informed or uninformed. It is rather a state where the information that is known by an individual cumulate to form a relative knowledge, where individual integrates information from multiple sources, each with different levels of accuracy and precision. When collecting information, animals can use a variety of non-mutually exclusive processes that can range from self-acquired to socially acquired information. Indeed, animals can gain information by direct detection via sensory systems, where information is based on environmental cues detected within an individual's perceptual range. In the animal realm, a variety of sensory systems have evolved to access information at different spatial scales with varying levels of accuracy. By combining inputs from different systems, animals may be able to increase the detection, accuracy, and quality of the information they can obtain (Spiegel and Crofoot 2016). Animals can also rely on their own experiences to gain information, which take the form of memories. Evidence of the use of memory as an information base to make a decision can be found in studies looking into foraging strategies, for example, repeated visits by animals to particular locations are often seen as the evidence of

memory use (Bracis et al. 2015; Merkle et al. 2014). Animals can also rely on others to obtain information about their habitat, either relying on conspecific or hetero-specifics. Socially acquired information can be based on others' sensory systems or memories. Indeed, by living in groups, individuals can gain access to the sensory information detected by other members, which can increase their detection range beyond their own physiological limitations and help improve the quality and accuracy of an individual's knowledge. Predator detection is a perfect example of such a situation as more individuals have more chances to detect a predator. On the other hand, member of a group can benefit from the experience of older members that possess more information about the habitat. For example, such reliance on others' memory can be seen in-group movement when older individuals lead the group movement toward a foraging destination (Teichroeb et al. 2012).

In addition to the different processes by which animals can reach an informational state, a set of decision rules have evolved to guide animals' decision-making (Owen et al. 2017). For example, a decision could be made using an absolute valuation rule, where the decision-making process includes an independent assignment of a fixed value to each option and where the decision is based on a trait meeting a specific criteria value taking the form of a "must have" (Jennions and Petrie 1997). For example, when choosing a mate, a decision based on an absolute value could take the form of a female assigning a fixed value to the weight of each male and then choosing the male that has the desired weight. A decision could also be made using comparative valuation, where a decision is based on the simultaneous comparison of the relative value of a trait on two or more options (Reaney 2009). In this case, the value assigned to each option is dependent on those it is compared with, rather than being an absolute value of its underlying characteristic. In this case, a female would simultaneously compare the attributes of two or more males and choose the one that has the desired weight in comparison to the others. Another rule that could be used is best-of-N choice. In this case, a comparison of a fixed

number of options is made, and the decision result on the choice of the "best" quality option is evaluated (Janteos 1980). A threshold can also be used, where a sampling of option is continuously made until a threshold value of a particular trait is found. In such case, a decision takes the form of a "must at least have" where the decision-maker would continue to search until it found what it was looking for. Finally, heuristic rules of thumb are used when a decision is made on incomplete information, which makes it a fast and frugal approach to information gathering (Owen et al. 2017). Indeed, heuristics are cognitive processes that provide a shortcut to animal decision-making via gathering partial information from all that is available (Hutchinson and Gigerenzer 2005). Since it is impossible for animals to evaluate all the possible options when facing a choice or to acquire all the information available in their environment, heuristic rules of thumb may be adaptively advantageous as it limits the amount of time and energy an organism has to invest to gather information and make a decision. Therefore, heuristic rules could enhance decision-making efficiency but limit its accuracy (Gigerenzer and Geismmaier 2011). Moreover, while heuristic rules of thumb allow one to make decisions based on partial information, simple rules of thumb can be followed to make a decision and can take the form of following simple rule such as "always forage when your resources drop below a threshold or when the other animal forages" (Conradt and Roper 2005).

## Collective Decision-Making

While solitary animals often make decisions by themselves on a daily basis, members of a group in social species often make collective decisions. To do so, a group can use different types of decisions that can use different processes and mechanisms. Two types of decisions have been proposed to occur within a group (Conradt and Roper 2005). The first one being a combined decision where group members choose individually, but not necessarily independently, between two or more options without the goal to reach a

consensus. In this case, the group's action emerges from the combined results of the decision of each member, which affect the group as a whole. A combined decision could take the form of task allocation in eusocial species, where insects allocate themselves tasks according to the local necessity (Beshers and Fewell 2001) or individuals deciding to either stay or leave a group in fission-fusion societies (Sueur et al. 2011). In such a case, the processes used by a single individual to make a decision could be involved in the decision-making process of the group. In contrast, the second type of decision, a consensus decision, occurs when members of a group choose between two or more mutually exclusive options with the specific aim to reach a consensus. In such a case, more than one individual can participate in the collective decision-making, which can involve different decision-making processes and mechanisms than the one used by an individual alone. For example, this type of decision can occur when a group has to decide which activity to engage in and at what time, as well as when and where to travel.

## Consensus Decision

Consensus decision plays an important role in social species as it allows the group to make decisions as a whole. This enhances cohesion and avoids a split that could result in the loss of the advantages of group living. To reach a consensus decision, all members of a group are not always involved in the decision-making process. Different configurations exist in terms of the number of decision-makers, ranging from one member to all members of the group. Three types of configurations have been proposed in the literature: (1) an unshared decision where a single (usually dominant) individual imposes its choice on the group; (2) an equally shared decision, where all group members have the same opportunity to contribute to the decision, independent of their identities or social status and where consensus is usually reached via a quorum or a vote; and (3) a partially shared decision, which can range from "little" to "widely" shared, where several group

members contribute more than others or make the decision for the group (Conradt and Roper 2005). In partially shared decisions, a subgroup is typically a demographic subset of members such as all males, all females, or all adults.

In addition to the configurations that can affect the decision-making process, Conradt and Roper (2005) highlighted two important aspects to consider in consensus decisions as they can also affect how a decision is made: the presence of conflicts of interest and the type of communication found in a group. Indeed, if a decision involves conflicts of interest, it can influence which members contribute to the decision-making process and affect the fitness consequences of different group members. The type of communication, either global, where all members can communicate together, or local, where a group is too big and only communication with near individual is possible, can influence group members' contributions to the decision as well as the type of decision-making mechanism involved.

In a group, conflicts of interest about the outcome of a decision emerge from the existence of consensus costs. Individuals differ in their characteristics like age, sex, and internal states, such as their level of satiety or reproductive status (Petit and Bon 2010). This can create differences in their personal needs and make them differ in their optimal timing of activities and location preferences. Thus, consensus costs emerge from the necessity to compromise with other group members (Conradt and Roper 2005), where the fitness costs will increase with the difference between the optimal timing and movement location of an individual and the actual timing and destination of its group (Conradt and Roper 2010). Because consensus costs exist and are distributed unequally within a group, conflicts of interest can emerge. These conflicts can cause different actors to attempt to participate in and influence group decisions to their own advantage, which in return can influence which mechanisms are used to make collective decisions and which group members contribute to the process. The presence or absence of conflicts could influence the exchange of decision-related information between group members (List 2004), the degree of

cooperation during decision-making (Couzin et al. 2005), and the fitness consequences of the decision outcome to individual members (Conradt and Roper 2005).

As for communication, it can affect the participation of members or the mechanism available to reach a consensus. Groups with local communication usually have to rely on what is called self-organizing rules, while in a smaller group that can rely on global communication more complex negotiating behavior can occur (Conradt and Roper 2005). Indeed, on the one hand, small groups such as those found in social primates, carnivores, or ungulates can usually use direct communication with all group members. Therefore, complex negotiating behaviors and coalitions could occur during consensus decision-making, taking the form of a vote or quorum, as the needs for such strategies are met. Direct communication can allow the opportunity for all group members to vote and be taken into consideration in the “counting of votes,” as well as allowing them the possibility to influence the decision of other members. Some examples of “voting” in animals include the use of specific vocalizations (Boinski and Campbell 1995), ritualized signals (Black 1988), body orientation (Conradt and Roper 2003), and following an initiator that propose a change of activity at the start of a group movement (Byrne 2000). Counting the vote could be done by adding up to a majority of votes or the integration of voting signals until an intensity threshold is reached (Conradt and Roper 2003). However, the voting system seems to be following a majority of “vote” rules, where consensus decision is reached via a quorum. A quorum is then the minimum number of group members that need to take or favor a particular option for the whole group to adopt this action (Conradt and Roper 2005). For example, in collective movement, decision-making starts with the departure of the first individual, called the initiator, that moves a distance exceeding a fixed threshold away from the group, sometimes including a specific posture (Bourjade and Sueur 2010). This initiator proposes a time and a direction for the group movement, and others can take part in the decision-making process by deciding to follow or not

(Petit et al. 2009). The need to actively recruit and the speed with which individuals follow can be influenced by factors such as their relationship with the initiator, and these will decrease as the number of followers increases until a quorum is reached and the group movement takes place.

On the other hand, in large groups, such as large flocks of birds, shoals of fish, herds of mammals, or colonies of social insects, direct communication between group members is likely to be impossible, which brings the individual to depend on local communication with their direct neighbors to reach a consensus decision as a group. In such context, complex voting behaviors are unlikely to occur forcing members to rely on self-organizing rules as a mechanism to reach a consensus. Self-organizing rules include simple rules of thumb and thus are behavioral rules that individuals can follow using only local information, and these result in an organized group behavior without the need for global control (Conradt and Roper 2005). More specifically, self-organizing rules arise from members of a group following relatively simple rules like staying close to one another or mimicking the behavior of others, which create an organization within the group where a group can move in coordination or start an activity without the need to communicate with every member of the group. Indeed, in movement, to reach cohesive group navigation, simple rules of interaction can be used as a general mechanism. Examples of simple rules include alignment, where individual aligns their direction with other members, or attraction at long range and avoidance at short distance. A consensus and shared decision between all group members can be achieved without the need for complex mechanisms or advanced cognitive abilities, even in very large groups (Conradt and Roper 2005). Therefore, a collective decision can be reached in the absence of leader or global information in certain circumstances but can instead rely on the rapid propagation of local information about the motion, activity, or interest of the nearest neighbors (Petit and Bon 2010).

In addition to these decision-making mechanisms, other processes have evolved within groups to facilitate the reach of a consensus.

Indeed, local interactions are an inherent characteristic of group living and are an underlying mechanism of collective decision-making processes. Local interaction between individuals allows the extraction of information about group members' activity at a short range (Petit and Bon 2010), which in return facilitates synchronization of a group allowing members to reach a consensus. Being able to extract information from other group members may also induce an increase in the probability of performing behavior already present in the group by allowing anonymous mimetism between individuals. Anonymous mimetism is the propensity for an animal to act like their congeners, which increases with the number of individuals performing an activity. The occurrence of anonymous mimetism means that a single individual can influence all members of the group (Meunier et al. 2006), whatever their identity (King and Sueur 2011; Petit and Bon 2010). However, in social species, individual identity and social relationships can have an influence on mimetism and create a selective mimetism whereby some individuals, due to their age, status, knowledge, or relationships, will be imitated more often (King and Sueur 2011). Mimetic behavior is well known in animals' group (Petit and Bon 2010) and implies a positive feedback loop (Sumpter 2006) on collective behavior that allows the amplification of an activity. Thus, this mechanism can amplify the decision made by a few individuals and may be decisive when a quorum in a small group is needed to reach a consensus (Meunier et al. 2006; Petit and Bon 2010) or when local information has to spread within a larger group.

## Conclusion

Decision-making is the process by which animals choose between different options. Individuals can integrate different types of sensory information, cognitive mechanisms, and decision rules to reach a decision, whereas the collective decision of a group can include more complex mechanisms ranging from self-organization rules to complex negotiation behaviors. The variety of sensory

system, social organization, and environment found within animals has created a multitude of configuration of decision-making, which challenges your understanding of such a critical process.

## Declarative Memory

Carmelo P. Cubillas

Universidad a Distancia de Madrid, Madrid, Spain

Universidad Autónoma de Madrid, Madrid, Spain

## Synonyms

Explicit memory

## Definition

Declarative memory is a long-term memory system where the processes of acquisition, storage, and retrieval are activated voluntarily and consciously.

## Introduction

The study of psychological processes such as learning and perception or memory, among others, has been of interest to many authors throughout history. A considerable amount of theories have been proposed about how these

processes work, each of them having more or less empirical support, in many different areas of knowledge. Historically one of the most studied psychological processes that has remained relevant to this day to many researchers is memory. Memory could be defined as a neurocognitive capability that allows for encoding, storing, and retrieving of information (see Tulving 2000, for more information on the term memory). According to this view, the use of memory implies an initial encoding of information (acquisition), the storage of this information during a determinate time, and its posterior retrieval and use (Anderson 2000).

Although these three components seemingly participate in all memory tasks (Neath and Surprenant 2003), there are two main viewpoints aiming to explain the nature of memory. On one hand, some authors define memory as a unitary process and assume that it adapts its functionality depending on the situation (Masson and MacLeod 1992). In other words, these authors supported the idea that memory is a single system that could operate differently depending on the task at hand, the kind of information, the time available, the subject condition, or the instructions given. On the other hand, it has been argued that memory is composed of different systems and that each one is, or is not, activated in any given situation (Squire 1995). Beyond this theoretical debate (see Foster and Jelicic 1999, for a revision), the study of memory since the middle of the twentieth century supported the idea that, although there are common processes to all memory systems (Neath and Surprenant 2003), it is composed of different and relative independent systems and that each of them have their own characteristics.

## Systems of Memory

One of the first distinctions among the different systems that compose memory was made based on the amount of information stored and the time that this information remains (Hebb 1949). Firstly, short-term memory is defined as the kind of memory that stores information for a brief time lapse. The exact amount of information and the time that

it is stored depends on the task at hand, the participant's status, the kind of material used, and many other variables. However, it is accepted that short-term memory could store sets of five to nine elements during a time span of 15–30 s. On the contrary, long-term memory stores a great amount of information, indefinitely. The study of a list of randomly generated numbers, for example, 2-4-5-2-9-7-0-1-1-6-5, and its immediate retrieval could be an example of a short-term memory task. In contrast, long-term memory is used to remember, for example, the name of an old school friend or our telephone number. The distinction between long-term and short-term memory has been supported by studies in many different areas as experimental psychology, neuroscience or studies of patients, to name a few. A third memory system that could be differentiated in accordance with the time that information remains stored is sensory memory. This system keeps the information stored for whatever amount of time needed to be transferred from the perception of the stimuli to its arrival to short-term memory. This process takes just a few hundredths of a second (Walsh and Thompson 1978).

Atkinson and Shiffrin (1968) proposed a well-known memory model in which these three memory systems are integrated. These authors assumed that the information accesses memory through sensory memory, and only some of these pieces of information are transferred to short-term memory. This transfer of information seems to be mediated by an intentional process, and it only selects a small part of the information that is received from the world. Information in short-term memory can be forgotten by decay or replaced by new information. However, rehearsal can keep it active in this memory system. According to this model, the only information that could generate responses is the one that remains activated in short-term memory. An elaborate rehearsal can allow information to pass from short-term to long-term memory and be stored indefinitely. Finally, information can also be retrieved from long-term to short-term memory and, as it has been mentioned, generate a response. Although the model proposed by Atkinson and Shiffrin (1968) had a deep impact

on the study of memory, some data has been found to question some of its assumptions, such as the fact that transference of information through short-term memory is not needed for long-term storage (Shallice and Warrington 1970).

Furthermore, these three systems of memory, namely, sensory, short-term, and long-term memories, have been subdivided into other systems accordingly to some factors such as the type of information stored, the processing of the information, or the way in which the information is acquired, among others. Firstly, there are three systems, specifically sensory memory, iconic, echoic, or haptic, depending on whether the information is visual, auditory, or tactile, respectively. It has been also noted the difference between short-term memory and working memory. It is assumed that while working memory could operate with the stored information, short-term memory only stores and retrieves information without modifying it (Cowan 2008). Adding numbers could be an example of working memory because it requires the individual to keep the information active and operate with it. Finally, a division of long-term memory has been proposed which attends to the kind of processes that carry out the acquisition, storage and retrieval of the information. Moreover, a division of long-term memory has been made depending on whether these processes are activated automatically or if participant's will is required. Following that criterion, long-term memory could be divided into two different systems: non-declarative memory and declarative memory.

### **Declarative Versus Non-Declarative Memory**

Non-declarative memory, also known as implicit memory or procedural memory, is defined as the system of memory that does not allow the conscious access of information stored; it has a slow acquisition process and is relatively inflexible. Non-declarative memories are acquired and used unconsciously and automatically but, despite this, can have a broad impact in our behavior. Implicit memory could also be divided into other minor

systems like the system needed for learning skills and habits or the system for the conditioning of emotional responses. Nonetheless, the most noted implicit memory system is the priming one. In a broader sense, the priming effect consists of the influence of a stimulus previously presented in response to other stimuli without the participant's awareness (see Geva et al. 1997). For example, knowing how to read or ride a bike is a model of non-declarative memories, more specifically procedural memories.

In contrast, declarative memory, also known as explicit memory, is defined as the long-term memory system in which the process of acquisition of information, storage, and retrieval is carried out consciously and voluntarily. These processes are learned rapidly and are more flexible than implicit memory. Declarative memory acquisition and information retrieval are made intentionally, and the information stored could be formulated as propositions or images. Knowing a phone number, a recipe, or the way home or to work is an example of declarative information.

The distinction between declarative and implicit memory has been supported by several studies. For example, different authors argue that amnesic patients who present problems acquiring or storing declarative memories do not present problems to acquire motor (Brooks and Baddeley 1976), perceptive (Cohen and Squire 1980), or cognitive skills (Squire and Frambach 1990). It has also been found that the priming effect appears in amnesic patients (Musen and Squire 1992). In the view of these findings, it could be argued that non-declarative memory is less prone to forgetfulness than declarative memory. Finally, some authors have proposed that the brain areas that are activated in both systems are different. The most well-known study on this matter is the description that Milner (1966) made about H.M. This patient presented significant deficits in retrieving events that occurred after a brain operation. He could however learn some procedures such as motor skills although he did not remember having learned them. During the operation, H. M.'s hippocampus, hippocampal gyrus, and amygdala were removed. These structures seem to affect the declarative but not the non-

declarative memory. This case reveals that the brain areas involved in both systems of memory are different and, also, suggests that those systems are independent. Taking all these studies into account, it can be supported that both systems, declarative and non-declarative, are quite different.

## Two Kinds of Declarative Memory: Semantic and Episodic Memory

More than the memory division exposed above, a distinction has also been proposed between two subsystems of explicit memory depending on the kind of information stored (Tulving 1972). These criteria differentiate between episodic and semantic memory.

Semantic memory stores general information, that is, information that has been learned in the course of our lives and that represents reality and general knowledge. The color of lemons, the order of the numbers, and the name of the capital city of a country are examples of semantic memories. In contrast, episodic memory is a type of declarative memory that stores information such as events, where, how, and when they occur. The most well-known definition of episodic memory was provided by Tulving (2002) who defined this memory system as “a travel back in time.” Examples of episodic memory are the memory of a birthday party, a trip made in holidays, or a match played by your favorite team.

A kind of declarative memory is an autobiographical one. It is defined as the storage of information about ourselves, and it is composed of episodic and semantics memories. Autobiographical memory stores all events that have occurred in our lives and all the information about us. However, although some authors have formulated theories about the principles and functions of autobiographical memory (e.g., Conway 2005), nowadays it is not clear whether autobiographical memory is really different from episodic memory (Markowitsch and Staniloiu 2011), whether it is a subtype of episodic memory (Fivush 2011) or an independent system of memory on its own (Conway and Pleydell-Pearce 2000).

Some authors have criticized the distinction between episodic and semantic memory (McKoon and Ratcliff 1986). However, the distinction of these two systems has been supported through several studies. For example, Spiers et al. (2001) described 147 amnesic patients that presented problems with retrieving episodic memories but not semantic ones. On the contrary, patients have been described to have deficits in semantic but not in episodic memory (for a revision, see Kapur 1999). Despite this, it is usually assumed that, as declarative memory is more sensitive to forgetting than implicit memory, episodic memory is also more easily forgotten than semantic memory. For example, it is more difficult to retrieve the memory of a moment or the context in which the meaning of a word was learned than the meaning of that particular word. Moreover, neuroimaging studies have found that the acquisition of episodic and semantic memories are not activated in the same brain areas, the same way that retrieval episodic or semantic memories are (Wheeler et al. 1997).

However, despite this distinction, it has also been argued that these two kinds of long-term memories are not totally independent from one another and that they could operate jointly. One of the earliest authors proposing this idea was Tulving (1972) who argued that the acquisition of new episodic memories were affected by the information stored in semantic memory. Other authors have proposed a different relationship between semantic and episodic memory. For example, Baddeley (1988) defined semantic memory as the information abstracted and dissociated from various episodic memories (for more studies that propose interdependence between semantic and episodic memory, see Reder et al. 2009; Mayes and Roberts 2001). In light of these studies, it is clear that these two memory systems operate, to a certain extent, jointly and that memories stored in both declarative memory systems are related in some way.

Finally, keeping in mind that the division of the different memory systems is not supported by all authors, declarative memory could be defined as the kind of long-term memory that is acquired, stored, and retrieved consciously and voluntarily.

Declarative memory could be divided into three subsystems: semantic, episodic, and autobiographic memory, each of them storing general knowledge, information about events or the information about ourselves.

### Synonyms

Conditioned defensive burying paradigm; Shock probe defensive burying; Shock prod defensive burying

### Definition

The defensive burying test is used by researchers to measure an animal's naturally occurring anxiety-like behaviors toward an aversive stimulus.

When an animal encounters a potentially threatening stimulus, the animal engages in a variety of behaviors to distance themselves from or reduce the risk of interacting with the noxious stimulus. A common behavior that rodents exhibit to reduce the threat of a potentially harmful stimulus is to bury the stimulus; this behavior is referred to as defensive burying. Rodents display this behavior in their natural environments, using their forepaws and heads to shovel available materials (e.g., leaves, bedding) onto or near the noxious object. Scientists have simulated this ethological behavior in the laboratory by exposing the animal to a noxious stimulus and measuring subsequent behaviors. The defensive burying test provides valuable knowledge regarding

emotional states and has been used as a screen for potential therapeutic treatments for anxiety-related pathologies (De Boer and Koolhaas 2003; Pinel and Treit 1978).

Burying behavior toward an aversive stimulus has been studied since 1950, when rats were observed covering an electrified food cup with available wood shavings (Hudson 1950). Over decades of testing, laboratory studies have used electrified shock probes, noxious odors, or noxious tastes as the harmful stimulus, although novel, non-threatening objects, like marbles, may also provoke burying behavior (Pinel and Treit 1978). In the laboratory, a standard defensive burying procedure occurs in a rodent's cage with a shock probe inserted through the cage wall. Upon touching the shock probe, the rodent receives a single electric shock and subsequently engages in behaviors to avoid further interaction with the shock probe, most commonly burying the shock probe with any materials available, such as cage bedding (Korte et al. 1992; Pinel and Treit 1978).

The defensive burying test has been useful in research to understand certain emotional states (e.g., state or trait anxiety, fear). The central behaviors assessed during the defensive burying test are frequency of and duration spent burying the shock probe with increases in either indicative of greater levels of anxiety (De Boer and Koolhaas 2003; Pinel and Treit 1978). The height of the bedding pile is frequently measured with taller bedding piles also suggesting greater anxiety. The latency to begin burying the probe following the shock can be measured as well, but the interpretation is less clear as there is a great degree of individual variability in burying versus freezing behavior (discussed below). Moreover, many additional behaviors can be assessed during the test and therefore, the defensive burying test provides researchers with multiple measures of assessing an animal's anxiety-like behaviors. The rich array of behaviors can provide researchers with a more complete picture of the rodent's behavioral repertoire, such as risk assessment/probe exploration (approach and withdrawal movements directed towards the shock probe), immobility/freezing as a measure of passive avoidance, grooming as a conflict behavior, and

rearing as a measure of escape attempts (for review see De Boer and Koolhaas 2003).

The behaviors displayed by the rodent to reduce the threat of a noxious stimulus can be categorized into active and passive coping behaviors. Active behaviors such as the time spent burying compete with passive behaviors such as freezing; and the two behaviors cannot be exhibited simultaneously but both may be indicative of an anxiety-like state. A lack of burying behavior does not necessarily indicate a lack of anxiety or fear in the animal; the animal may simply be engaging in other behaviors to cope with the stimulus, like freezing. By assessing the entirety of the animal's complex behavioral repertoire, the defensive burying test provides a more nuanced method for assessing highly specific behaviors and the timeline of the behavioral responses. The degree to which an animal expresses these active and/or passive behaviors can be indicative of adaptive coping responses and/or maladaptive behaviors. The test is typically utilized as an unconditioned measure of anxiety-like behaviors within a single day of testing in the animal's home cage. The test is flexible, however, because further trials on subsequent days can be conducted to assess the conditioned response to the shock probe; conditioned testing may provide alternative information of anxiety and fear-related pathologies (De Boer and Koolhaas 2003).

The use of the defensive burying test to assess anxiety-like behaviors in rodents has been validated by pharmacological evidence with known anxiolytic and anxiogenic agents and therefore can be utilized for screening pharmacological agents with therapeutic potential. In humans, treatment for anxiety commonly includes anxiolytic agents such as diazepam or other benzodiazepine compounds. The same types of drugs (e.g., diazepam, benzodiazepine, midazolam, and pentobarbital) administered acutely decrease rats' defensive burying behavior toward a shock probe and increase contacts with the probe compared to control animals (Treit 1990; Tsuda et al. 1988). On the other hand, known anxiogenic pharmacological agents increase burying behaviors. For example, rats injected with yohimbine, an  $\alpha_2$ -adrenergic antagonist known to induce anxiety in humans (Charney et al. 1983), spent significantly more time engaged in burying behavior compared to

control rats (Tsuda et al. 1988). Together, the effects of anxiolytic and anxiogenic drugs provide evidence that behaviors displayed in the defensive burying tests are appropriate indices of anxiety.

The shock probe defensive burying test has also been validated by physiological measures associated with a sympathetic response to a dangerous/harmful stimulus and comparable to human-state anxiety. Rats engaged in defensive burying behaviors towards a shock probe have higher plasma catecholamines and corticosterone than control, non-shocked rats (Sgoifo et al. 1996). This parallels the data that demonstrates that human states of anxiety have been positively correlated with urinary excretion of norepinephrine and cortisol as well as increased blood pressure (Charney et al. 1983; Hughes et al. 2004). It is important to note that the heightened stress response during the defensive burying test is not solely an acute physiological stress response to the shock itself. In a multiple trial defensive burying experiment, Korte et al. (1992) demonstrated that on the day following the shock, rats displayed a stress response when presented with a non-electrified probe. The stress response to the presence of the probe, rather than a stress response to the shock itself, provides evidence that the rats exhibited an increased anxiety-like state following shock probe exposure. This data parallels anxiety-like states in humans, which represent an unpleasant emotional response to a threatening or harmful stimulus.

In conclusion, the shock probe defensive burying test assesses an animal's complex behavioral repertoire in response to a harmful or threatening stimulus. Overall, the pharmacological and physiological research supports the use of the shock probe defensive burying test to measure anxiety-like behaviors in rodents and test the efficacy of potential anxiolytic therapeutic compounds. The use of this test in rodents provides clinical value in its usefulness of modeling human coping towards an adverse stimulus or states of anxiety.

- kinds of behavior ranging from complex tea ceremonies, to mimicking body movements are due to a sophisticated imitation capacity, or rather reflects a more general learning mechanism (Heyes 2016). This entry explores the distinction between immediate and deferred imitation to discuss the notion of a specialized imitation system versus a more general action-perception matching system from a developmental, neuroscientific, as well as a comparative perspective.

In the literature, a distinction has been made between immediate, or also-called on-line imitation where the imitator repeats the model at the same time, and deferred imitation, where the action repetition between model and imitator is delayed. Cognitive theorists highlight deferred imitation as a way of investigating long-term memory in preverbal infants (Meltzoff 1988). Deferred imitation is relevant to theorists because the infant or child will not always be able to reproduce each adult action as soon as it is demonstrated; thus, for imitation to fulfill its socio-cultural utility, the infant or child must be capable of initiating imitation in the absence of the model. Finally, Piagetians focus on deferred imitation as a developmental milestone that first emerges at about 18–24 months, as part of a general emergence of the “symbolic function” enabling representational behavior beyond sensorimotor control (Piaget 1952). For both immediate as well as deferred imitation, we first have to define what counts as imitation. Whereas some theories stress the fact that the movements of the model and the imitator have to share the same topographical characteristics to be labeled as imitation (Brass and Heyes 2005), other theories have stressed that imitation can also be seen as a more goal-directed copying behavior, where imitators copy the goal of an action rather than the movement themselves (Bekkering et al. 2000; Wohlschläger et al. 2003). Below, I will outline how this distinction might be less clear-cut than what has been argued before.

Imitation has a long tradition in developmental psychology and was used as a mean to get insights in cognitive human development. Guided by findings from Meltzoff and colleagues, it was stressed that topographical imitation is an inborn mechanism (Meltzoff and Moore 1977), newborns can

## Deferred Imitation

Harold Bekkering  
Radboud University, Nijmegen,  
The Netherlands

Our rich and diverse cultural landscape has arisen not only from our ability to innovate but also because we can copy others and build upon the knowledge of previous generations. This unique human ability to so diversely imitate has been coined *Homo imitans*. However, a debate has taken place whether our capacity to copy all

imitate facial and manual actions by means of an active intermodal matching systems in which proprioceptive information is matched in the observer from perceptual input to motor output. The notion of an inborn imitation mechanism was supported by neurological findings of so-called mirror neurons, i.e., neurons that fire both when an animal acts and when the animal observes the same action performed by another (Rizzolatti and Craighero 2004). As referred earlier, findings of Piaget indicate that deferred imitation can only take place around the second year of life, when children start to cook meals or are driving toy cars in similar manners as their parents do with their adult-size toys (Piaget 1952). Unfortunately, this division in development does not seem to hold. There is abundant evidence that newborns do not imitate in a topographical manner (Ray and Heyes 2011), and it has also been shown that we have limited capacities to imitate elementally novel actions over the whole lifespan (Heyes 2016). Also, follow-up studies of the mirror-neuron mechanisms showed that firing was not dependent on topographical characteristics but rather on goal-directed characteristics (Umiltà et al. 2001). Many cells fire in an effector-independent as well as a perceptually multimodal manner (Kohler 2002). In line with the notion that imitation serves the initiation of already known behavior, rather than learning novel actions, mirror neurons also typically respond to actions that are in the primate's motor repertoire, as is the case when they have learned to use pliers to grasp a peanut (Umiltà et al. 2008), although suggestions that mirror neurons can also derive from solely visual observations are also reported (Ferrari et al. 2005). To summarize, there is little evidence supporting the claim that an inborn mechanism serves imitation in newborns. Rather, on the basis of sensorimotor experiences, human infants learn to imitate immediately, or in a deferred manner. Clearly, the ability to imitate more complex actions depends on general cognitive capacities like working memory, and deferred imitation is used clinically to test amnesic patients for their loss of declarative memory (McDonough et al. 1995). The latter can be taken as evidence that imitation is not based on a

simple stimulus-response (S-R) association between model and imitator akin to topographical imitation accounts. However, contemporary associative learning theory will still stress that an imitative action can be produced in the absence of the stimulus on the basis of what observers have observed earlier (Heyes 2016). As a consequence, a certain motivational urge to produce an action when observing an acting model can be based on the expected consequences of performing a specific action rather than reproducing the specific action observed. Such an outcome-based view on imitation includes the observation that when children are confronted with an extraordinary action, i.e., somebody touches his ear with her contralateral hand, this might evoke a different action, activating the ipsilateral hand, to touch the ear (Bekkering et al. 2000).

There is little doubt that humans are more skilled and prolific imitators than other animals, but the question is whether this is related to a special, inborn "intermodal matching" mechanism that integrates representations of others with representations of the self, or if it reflects more general cognitive capacities is still open. There is ample evidence that other animals have some capacity for imitation and also that this is experience dependent. Chimpanzees, for instance, have been found that after learning a strict set of actions, they are well able to imitate novel but related arbitrary gestures (Custance et al. 1995). Interestingly, deferred imitation has also been found. Deferred imitation of novel actions was also found in dogs with retention intervals of 1.5 min and memory of familiar actions with intervals ranging from .40 to 10 min. In other animals, deferred imitation is not only based on sensorimotor-related stimuli. For example, observer budgerigars accessed a stopper immediately or 24 h after the observers had watched a video of a con-specific model either pecking or stepping on the stopper to obtain access to food. The observers performed the action they had observed, pecking or stepping, with higher frequency in both immediate as well as deferred imitation, suggesting that budgerigars are capable of "deferred imitation" or "imitation from memory (Richards et al. 2009)," a

capacity previously thought to be uniquely human (Meltzoff and Moore 1994).

In summary, this entry has briefly discussed important topics in the light of underlying mechanisms of deferred and immediate imitation. First, there is little evidence that a specialized imitation system enables immediate imitative behavior, while deferred imitation is based on more complex cognitive behavior. Rather, imitation always includes perceived outcomes of actions beyond simple S-R mappings. Additionally, evidence is lacking that early immediate imitation is initiated before active experiences are collected. Second, the supposed underlying mirror neuron mechanism is not serving immediate imitation only. The system includes higher cognitive representations such as outcome expectancies and also heavily relies on experiences. Finally, findings from comparative studies suggest that imitation goes beyond simple S-R mappings. Birds as well as other animals are found to be sensitive to rewards like food, which modulate immediate as well as deferred imitation. To conclude, humans are gifted imitators, and the capacity to defer imitation in the absence of the observed model marks us as members of particular cultural groups and contributes to cultural evolution, the accumulation of knowledge and improvement of skills over generations. However, the mechanisms that make imitation possible are not likely to be an inborn, special imitative system. Rather, we are great imitators, *Homo imitans*, as we can use previous experiences in a given situation to create the likely consequences of performing the action observed in others.

## Definition

The development of microdrives capable of recording electrical activity of individual neurons allows researchers to step away from the traditional method of brain lesions to examine brain function. Importantly, electrophysiology allows researchers to examine the ways in which information may be represented and maintained in neurons across different species and different regions of the brain. Many behavioral tasks designed to examine such mechanisms include a period of delay in which the subject is required to maintain task-relevant information to later guide successful behavior. Any neuron with changes in neural activity in either an “inhibitory” (decreased activity) or “excitatory” (increased activity) manner during a delay period when memory is engaged, relative to a period that does not require memory, is regarded as a delay neuron. Generally speaking, delay activity is considered a memory trace of either a stimulus that must be maintained, a position to which the animal must respond, or some upcoming plan of action, be it motor or non-motor.

Delay neurons are found not only in humans, but also in all nonhuman species examined, including primates, birds, and rodents. In all species, delay neurons have been identified in sensory-specific regions such as visual and auditory areas, areas that are important for processing

elements of stimuli to be remembered. As delay neurons are thought to represent memory, much research has also focused on sensory integration regions thought to be crucial for executive functioning, such as the prefrontal cortices, hippocampus, and their homologues in other species.

## Delay Neurons in Primates

Two early studies that adopted single-unit electrophysiology in nonhuman primate species found evidence of what we now call delay neurons. Kubota and Niki (1971) trained monkeys on a delayed alternation task to press either a right or left lever after a delay period that was opposite to the side they pressed before the delay period. Similarly, Fuster and Alexander (1971) trained monkeys on a delayed response task in which, after a delay, the monkeys had to displace the object over either the right or left food well that corresponded to where the object had been placed prior to the delay. Both studies reported neurons that fired during the delay period; however, despite the popular current view that delay activity represents the storage of information necessary to bridge the delay period, neither Kubota and Niki (1971) nor Fuster and Alexander (1971) favored the view that the delay activity represented a neural correlate of memory. In the case of Fuster and Alexander (1971), the reason was that they did not find any delay activity that was able to differentiate between a required left response and a required right response.

From the early work of Kubota and Niki (1971) and Fuster and Alexander (1971), primate research spawned two lines of delay neuron studies, one exploring the role of delay activity in the context of oculomotor-based delayed-response tasks, and the other exploring the role of delay activity in the context of delayed matching-to-sample (DMS) tasks. For a full review of the oculomotor-based response task literature, the reader is directed to a review by Funahashi (2017).

One of the most popular tasks used in studies examining the neural basis of memory is the delayed matching-to-sample (DMS) task. In a

standard DMS task, the subject is shown a sample stimulus, which is followed by a delay period. Following the delay period, the subject is typically presented with two comparison stimuli and must respond to the comparison stimulus that matches the sample stimulus it saw prior to the delay. In order to solve the task, the subject should remember the sample stimulus during the delay period. In the context of a DMS task, delay neurons in the inferior temporal (IT) cortex have been shown to be highly selective for a range of abstract stimulus features even across delays as long as 16 s (Miyashita and Chang 1988). In the Miyashita and Chang (1988) study, for example, delay activity occurred after some sample stimuli and not after other sample stimuli.

In IT cortex, a region dedicated to processing visual information, the delay activity is not surprisingly modality specific. Gibson and Maunsell (1997) trained monkeys on four DMS tasks simultaneously. The first was a standard visual DMS task with visual sample and visual comparison stimuli (visual-visual DMS). The second was a standard auditory DMS task with auditory sample and auditory comparison stimuli (auditory-auditory DMS). The remaining two DMS tasks were cross modal such that visual sample stimuli were symbolically matched to auditory comparison stimuli (visual-auditory DMS), or the auditory sample stimuli were symbolically matched to visual comparison stimuli (auditory-visual DMS). There were many selective delay neurons that were encountered in IT cortex, but only on the visual-visual DMS, visual-auditory DMS, and auditory-visual DMS tasks, and not the auditory-auditory DMS task. The fact that monkeys can solve visual-visual DMS, auditory-visual DMS, and visual-auditory DMS tasks (but not an auditory-auditory DMS task) by using visual memory confirms that delay activity in IT cortex is related to the processing of modality-specific visual information.

In the prefrontal cortex (PFC), delay activity is a code not only of working memory for the sample stimulus but also more abstract concepts essential in DMS and delayed nonmatching-to-sample (DNMS) task performance. For example, Nieder and Miller (2003) found many delay neurons that

coded complex numerical information. Monkeys were trained on a go/no-go DMS task using different arrays of 2–6 dots as stimuli. In their go/no-go procedure, the comparison stimuli appeared one at a time, and the subject was required to refrain from responding until the correct comparison stimulus appeared. The number of dots in the sample and correct comparison array were the same, but the position of the dots in the array were different, meaning the monkey could not rely on remembering the sample by remembering the arrangement of dots, but rather had to remember the number of dots in the array. A number of neurons in PFC were selective to specific numerocities (e.g., three dots) regardless of how the dots were arranged in the array. Such a finding demonstrates that delay neurons in PFC can code the value or number of dots rather than a specific arrangement of dots.

In addition to coding numbers, PFC delay neurons have also been shown to code the value of an anticipated reward. Watanabe (1996) trained monkeys on a spatial delayed-response task with differential outcomes (DO), such that the reward contingencies associated for one sample-comparison stimulus pairing was different to that of another sample-comparison stimulus pairing. Watanabe (1996) found neurons in the PFC that fired during the delay period of, for example, trials associated with a grape reward but not during the delay of trials associated with a potato reward. Later, Watanabe (1996) switched the reward contingencies such that the stimulus pairing associated with the grape reward was now associated with the potato reward and vice versa. After the switch, delay neurons appeared to continue to encode the identity of the upcoming reward (e.g., grape) regardless of the stimulus pairs that predicted it. Given that the stimulus pairing itself remained the same and only the upcoming reward had changed, the delay activity is indicative of a neural correlate for the upcoming reward.

PFC delay neurons have also been shown to code the rule that the animal must employ to solve a task. Much like a standard DMS task, in a DNMS task, the subject needs to use working memory to bridge the delay period in order to successfully respond during the comparison

period. However, the two tasks differ in that, in a DMS task, the rule is to respond to the comparison that matches the sample, whereas in a DNMS task, the rule is to respond to the comparison that does not match the sample. Wallis et al. (2001) trained monkeys on both DMS and DNMS tasks with a cue accompanying the sample presentation to indicate which rule was currently in operation, matching or nonmatching. For one monkey, either a drop of juice or a blue background signalled the match rule, and no juice or a green background signalled the nonmatch rule. For the other monkey, juice or a low frequency tone signalled the match rule, and no juice or a high frequency tone signalled the nonmatch rule. Delay neurons in the PFC selectively coded the rule such that activity during matching trials differed significantly from that of nonmatching trials, regardless of the stimuli used. Overall, neurons in the PFC are clearly involved in coding abstract concepts that underlie the successful performance of complex cognitive tasks.

## Delay Neurons in Birds

Unlike primates, avian species have eyes located on the side of their heads, making oculomotor tasks extremely difficult. Instead, delay activity in birds has been examined exclusively in the context of DMS tasks. Despite architectural differences, the avian entopallium is considered similar in function to part of the primate extrastriate cortex. Johnston et al. (2017a) found delay neurons in the entopallium during a DMS task, a finding that is consistent with the view that, much like delay neurons in IT cortex, delay activity in entopallium represents a sensory code of the sample stimulus.

With respect to higher order cognitive regions, the nidopallium caudolaterale (NCL) is thought to be equivalent to the PFC, with both regions sharing many similar cellular and projection patterns, as well as an impairment in cognitive flexibility and memory when lesioned (Güntürkün 1997). Johnston et al. (2017b) found that, much like the primate PFC, neurons in the pigeon NCL remain active throughout a delay period of a DMS task,

providing evidence that delay activity in NCL represents a neural correlate for the to-be-remembered sample stimulus. Similarly, Veit et al. (2014) trained crows on a basic DMS task and found that neurons in the NCL displayed differential activity during the delay period for each of the sample stimuli.

Neurons in the NCL, much like neurons in the PFC, code for reward as well as memory. Johnston et al. (2017a) found that NCL delay neurons tended to occur following the rewarded stimulus but not the nonrewarded stimulus, suggesting delay activity in NCL represents a code of the possibility of an upcoming reward, at least when reward outcomes can be used to bridge the delay period of a DMS task. Similarly, in a directed-forgetting version of a DMS task, where after the sample stimulus the subject is either told to remember or forget what they just saw, both Rose and Colombo (2005) and Browning et al. (2011) found delay activity in NCL following the remember cue but not the forget cue. Although such a finding could be interpreted as the sustained activation reflecting a neural correlate of the animal remembering the sample stimulus, the presence of delay activity following remember cue and the absence of delay activity following the forget cue could also reflect the fact that, after a remember cue, there exists the possibility of obtaining a reward, whereas, after the forget cue, no reward is forthcoming.

Like in PFC, NCL delay neurons also code abstract concepts essential for performance of a DMS task. Wagener et al. (2018) demonstrated that many delay neurons in the crow NCL not only code the sample stimulus but also selectively code numerical values from complex stimuli in a DMS task, even when untrained on numerical matching. Much like the procedure used in Nieder and Miller (2003), crows were presented with stimuli containing different dot arrays. The crows were trained to match the color of the dot arrays while not needing to remember how many dots were in the array. While the crows appeared to be behaviorally selecting based on color of the dot arrays, neurons in the NCL were spontaneously and selectively coding the different numerical values of the stimuli. Such selective activity during a

delay period, similar to that found in primate studies with comparable procedures, provides the strongest evidence that delay neurons represent a neural correlate of the to-be-recalled sample stimulus.

Finally, similar to the Wallis et al. (2001) study showing that PFC neurons can also code abstract rules, Veit and Nieder (2013) isolated delay neurons in the crow NCL during an abstract rule DMS task. For each rule, either a visual cue or an auditory cue was presented and indicated whether the crow would be required to solve the DMS task on the basis of a matching rule or a nonmatching rule. As for PFC, many delay neurons in NCL selectively coded the behavioral rule and did so irrespective of the modality of the cue signalling the rule. Furthermore, cue selectivity was weaker during incorrect trials, indicating the neuronal coding was somewhat predictive of the bird's behavioral responses. Overall, the delay neuron findings for birds closely mirror those reported for primates.

## Delay Neurons in Rodents

The poor eyesight of rodents and their quadrupedal body makes it difficult to use picture stimuli on touchscreens for DMS/DNMS tasks like those used in primate and bird experiments. However, a variety of tasks to probe working memory of a stimulus or past event in rodents have been developed. One such task is the delayed spatial alternation task. Generally, rodents are placed in a T- or Y-shaped maze in the central stem for some delay. After the delay, rodents must travel up the stem and choose the opposite arm they travelled on in the previous trial. Thus, rats must keep their previous choice in working memory to successfully complete the task. A second variety of widely used working memory tasks for rodents has a series of levers and utilizes some sensory cues, such as lights or auditory tones, that indicate which specific lever must be pressed in order for the rodent to receive a reward. Rodents wait in a holding area while the cue is given, then are held there for a delay period before they are able to make their choice. Other simplified setups involve

two levers, where rodents are presented with one of the levers and, after some delay, are presented with both levers and must choose the opposite lever (DNMS) to what they were presented as the sample. Following the discoveries of delay neurons in the primate brain (Kubota and Niki 1971; Fuster and Alexander 1971), researchers utilized these rodent-designed tasks to investigate whether rodents also possessed delay neurons.

Sakurai and Sugimoto (1986) pioneered rodent working memory tasks and the neurophysiology necessary for optimal performance. They developed a DNMS task where a pure tone indicated to the rats that they could make a “go” or “no-go” response on a small panel. In order to be rewarded, rats had to carry out the opposite response (nonmatch) from the previous trial. Following primate work (Fuster and Alexander 1971; Kubota and Niki 1971) showing that the PFC and thalamus contained delay neurons, Sakurai and Sugimoto (1986) found single units in both brain regions in rats that responded during the delay period. These units responded differently whether or not the rat was going to make a “go” or “no-go” response. Strikingly, DNMS delay activity was predictive of the rats making correct or incorrect responses. A subsequent study by Batuev et al. (1990) confirmed the presence of delay neurons in the PFC in a cued DMS task where delay neurons also encoded the upcoming choice based on the cue during a delay. These data demonstrated that rodents not only have delay neurons but that the delay neurons in these regions maintain upcoming action plans.

A number of delay neuron studies have also recorded activity from the hippocampus. The hippocampus is a well-known brain region for its vital role in memory encoding and long-term consolidation. Following the discovery of delay neurons in the PFC and thalamus, researchers investigated the role of the hippocampus in working memory tasks and if it too possessed delay neurons. Sakurai continued his rodent delay neuron investigation by recording hippocampal units (CA1, CA3, and dentate gyrus subregions) along with neurons from the motor cortex (Sakurai 1990b) and auditory processing brain regions (Sakurai 1990a). In an auditory tone-cued

continuous DNMS task, neurons in the hippocampus, auditory, motor cortices, and medial geniculate body (MGB) showed sustained activity during the 3 s delay. Auditory cortex and MGB likely encoded sensory traces of the tone the rats had to keep in working memory (Sakurai 1990a). Furthermore, motor cortical units likely encoded upcoming motor plans as these units were especially active on trials where rats had to respond. However, despite Sakurai (1990b) finding some hippocampal delay neurons, these neurons were quite rare (<20% of recorded hippocampal units). Rather, hippocampal single unit activity was most active just before the rats initiated their responses on correct trials. This may indicate hippocampal retrieval of mnemonic information from the past trial to compare to the current trial and make the appropriate response.

Others continued to build on Sakurai’s work investigating the role of the hippocampus in working memory. Otto and Eichenbaum (1992) conducted a similar experiment that utilized odors instead of auditory tones and used a longer 6 s delay between stimulus presentations. They too recorded hippocampal CA1 single units during the task and found that approximately 20% of recorded CA1 units displayed delay-related activity. However, only 13% of these delay neurons had differential firing on future correct versus incorrect responses. Many subsequent studies, primarily carried out by Hampson and Deadwyler, have confirmed that the hippocampus (CA1 and CA3) was sparsely populated with delay neurons whose individual activity poorly predicted correct or incorrect responses (Hampson et al. 1993). However, subsequent investigations into CA1 and CA3 units using simultaneously recorded large populations of neurons showed that hippocampal population activity during delay periods was indeed predictive of correct versus incorrect responses (Hampson and Deadwyler 1996). Furthermore, during incorrect long delay ( $\geq 15$  s) trials, hippocampal population activity decayed and carried less information about the past cue and upcoming response. This decay of information maintained in hippocampal ensembles was correlated to the rats’ poor performance on long delay trials. Overall, these data indicate that ensembles

of hippocampal neurons encode and maintain task-relevant information, which may aid in successful decision making when previous stimuli must be maintained in working memory.

## Delay Neurons in Humans

A number of early studies in humans implanted with depth electrodes for identifying the locus of epileptic seizures for subsequent surgical resection reported that stimulation of various regions in and around the medial temporal lobe resulted in the recall of auditory and visual events (Penfield and Perot 1963). Later studies took advantage of more modern scanning techniques. For example, Maguire et al. (1997) used PET to examine the neural basis of topographical memory retrieval and found that recalling complex routes resulted in the activation of the right hippocampus. Similarly, fMRI Studies revealed that maintenance of a percept results in activation of the prefrontal cortex and hippocampus, whereas perception of the same percept results in activation mainly in occipito-temporal areas (Portas et al. 2000).

Despite the enormous number of studies that have explored the neural basis of different types of memory using a variety of different scanning techniques, few have examined the neural basis of memory at the single-neuron level using techniques and tasks similar to those encountered in studies with monkeys, birds, and rodents. Perhaps the one study most similar in format to those conducted with nonhuman species was by Halgren et al. (1978) who recorded from single neurons in the hippocampus and amygdala while patients performed a DMS task. Halgren et al. (1978) did find delay activity, although unlike the situation that has been noted for monkeys, birds, and rats, in none of their 267 units was there a case where the activity was restricted to the delay period compared to the other periods.

It is possible that the difficulty in encountering delay neurons in the aforementioned studies may be due to the fact that most recordings have been conducted in the medial temporal lobe region, whereas most reports of delay activity in monkeys and birds (but not rats) have been conducted in

visual cortex, prefrontal regions, and auditory regions. Indeed, although the tasks and procedures were slightly different to those used with nonhuman subjects, a number of studies have reported neural correlates of memory when the recordings were made in the lateral temporal (visual) cortex of patients (Haglund et al. 1994).

## Contemporary Issues in Delay Neuron Research

Animals are typically tested on DMS tasks for many trials within a daily session. The common convention for examining delay neurons is to pool activity across all trials. It has recently been argued, however, that delay activity should be examined on a single trial basis. At the core of the debate is how information is maintained in delay periods, and whether information is stored in bursts of spiking activity (asynchronous bursts) or persistent activity (spiking maintained across the entire delay) (Constantinidis et al. 2018; Lundqvist et al. 2018).

Those in favor of spiking activity argue that, although it is possible to see persistent activity on a single neuron basis, for many neurons, the spikes are not consistent throughout a delay period (Lundqvist et al. 2018). Furthermore, of the few neurons that do show persistent activity on a single trial basis, those selected as example neurons are cherry picked and not representative of the group of neurons as a whole. Additionally, individual neurons do not always maintain activity levels that occur in response to sensory inputs from sample stimuli, suggesting that single neurons do not respond to stimuli and maintain a neural correlate for that stimulus throughout the delay (Lundqvist et al. 2018). The argument to examine bursts of spiking activity in single trials is that information is thought to be coded in a larger network of neurons, each contributing to the maintenance of task relevant information. Maintenance is therefore more robust and less likely to be interrupted, and the brain is able to conserve energy when each neuron is not continually spiking (Lundqvist et al. 2018). Importantly, single trial analysis retains temporal information,

which can be lost when activity is pooled across trials, allowing researchers to examine how networks of neurons coordinate to maintain information when using modern multichannel electrodes (Lundqvist et al. 2018). In summary, those in favor of spiking activity argue that the “seemingly” persistent delay activity is an artifact of averaging, and by averaging, the intricacies of neuronal networks and what information is being conveyed by delay neurons can be lost.

According to those that favor persistent activity, trouble with examining spiking bursts arises when spiking activity is sparse and variable between trials (Constantinidis et al. 2018). Without averaging across trials, one might not see the impact of the neuron as they do not have enough spikes in a single trial for a comprehensive analysis. Furthermore, proponents of persistent activity argue that varying patterns of persistent activity have frequently been predicative of behavioral outcomes, and that such an effect is much harder to determine in the sparsely firing spiking activity analysis (Constantinidis et al. 2018).

Averaging across trials for persistent activity is a completely reliable and robust method for analysis that has continually yielded consistent measures of delay activity. However, there is merit in examining spiking activity, as it allows for a more comprehensive analysis of temporal information in neuronal recording. As such, both techniques yield important information as to how and when information is coded in delay neurons.

## Summary

Delay neurons have been isolated in many species and across many different brain regions. Generally speaking, what the delay neurons represent tends to be largely influenced not only by the brain region in which the neurons originate but also by the parameters of the experiment. In sensory regions, delay neurons appear to represent a neural correlate of the working memory of the sample stimuli. In sensory integration regions, or regions implicated in higher-order cognitive functions, delay neurons appear to code more complex

aspects of the task. In simple DMS tasks, delay neurons in higher-order cognitive regions may reflect a neural correlate of the sample stimuli. However, more neurons in such regions seem to prospectively code reward anticipation, abstract rules, and go/no-go behaviors. Furthermore, for many of the experiments demonstrating such neurons, the delay activity levels often correlate with the behavioral performance of the subjects. Although task parameters are adapted to suit different species, properties of delay neurons appear to be remarkably similar across species, suggesting the delay function of neurons to be evolutionarily preserved.

## Delay of Reinforcement

Thomas DiBlasi and Cecily Portillo

### Keywords

Delay discounting · Response acquisition ·  
Response maintenance

### Definition

*Delay of reinforcement* occurs when a period of time has elapsed between the response and the administration of the reinforcer.

Reinforcement is defined as the presentation or removal of a stimulus following an organism's response that results in an increased probability that the response will reoccur. For example, when a rat presses a lever and receives food, the rat learns that pressing the lever produces a desired result (food). The presentation of food (the reinforcer) increases the likelihood that the rat will press the lever again in the future. There are a number of factors that impact the efficacy of reinforcement, one of which is the delay of reinforcement. *Delay of reinforcement* occurs when a period of time has elapsed between the response and the administration of the reinforcer. For example, if a rat presses a lever that instantly releases food, the rat receives immediate reinforcement since no time has elapsed between the response and the reinforcement. The passing of any time between the lever press and the delivery of food would qualify as delayed reinforcement.

## Parameters of Delayed Reinforcement

There are several important parameters of delayed reinforcement. One parameter of delay of reinforcement is the contiguity between the stimulus and the reinforcement. As the delay of reinforcement increases, the contingency decreases, thus leading to a reduction in the response rate. An immediately reinforced response leads to a strong association between the target response and the contingency (i.e., the reinforcer). When reinforcement is delayed, there is a weak association between the target response and the reinforcer. Oftentimes the response(s) that precedes the reinforcer has a stronger association with the reinforcer than the target response, thereby decreasing the perception of a contingency between the target response and the reinforcer. However, very short delays (0.5–2 s) of reinforcement have been found to lead to similar response rates, if not higher response rates than immediate reinforcement (Dews 1981; Sizemore and Lattal 1978). A rat that is immediately reinforced for pressing a lever is not only more likely to press the lever in the future but also more likely to press it at a higher rate than a rat that is on a 10-second (s) delay of reinforcement.

In addition to contiguity, delayed reinforcement can be affected by the delays being fixed or variable. *Fixed delayed reinforcement* (Sizemore and Lattal 1977) requires that the amount of time between the response and the reinforcement stays constant throughout the experiment. Delay of reinforcement could be fixed at 10 s, meaning the organism will not receive the reinforcer until 10 s have elapsed following each response. *Variable delayed reinforcement* (Sizemore and Lattal 1977) allows the time between the response and the reinforcement to potentially vary across trials. Variable delayed reinforcement of 10 s means the average elapsed time across all trials is 10 s; however, one trial of delayed reinforcement could involve a 1-s delay, while another trial could involve a 19-s delay.

Another parameter of delayed reinforcement is whether the delay is signaled or unsignaled. A *signaled delay of reinforcement* (Ferster and Skinner 1957) involves the presentation of an

additional stimulus to indicate a delay period preceding reinforcement. Take a pigeon that is on a 10-s delayed schedule of reinforcement for pecking a green light when it is presented. In a typical signaled delay of reinforcement study, the pigeon will peck the green light, the cage will be blacked out during the delay (the signal is the blackout), and the pigeon will receive the reinforcer after the 10-s have elapsed. A signaled delay of reinforcement can be understood as a chain schedule because it presents an additional stimulus during the delay period, thereby creating a chain of stimuli. An *unsignaled delay of reinforcement* (Ferster and Skinner 1957) is when a delay period is not preceded by additional stimuli to indicate its onset. In the aforementioned example, the pigeon would not experience the blackout; rather, only the stimuli that were presented before the pigeon pecked the light would be present after the pecking response. An unsignaled delay of reinforcement can be conceptualized as a tandem schedule, which means that each component (i.e., stimulus, response, delay, and reinforcement) follows another.

A fourth parameter of delayed reinforcement is the occurrence of a superfluous response during the delay of the reinforcer. A response during the delay period may cause the organism to be penalized, resulting in the restarting of the delay period. This is known as a *resetting delay* (Lattal 1987). In a 10-s resetting delay, a pigeon that pecks the green light within that 10-s delay period will cause the delay period to restart. The pigeon must not respond during the 10-s delay in order to receive the reinforcer at the end of the delay. A *non-resetting delay*, on the other hand, will not be affected by a response during the delay period (Lattal 1987). Once the organism has made the reinforcing response, any responses that occur during the delay period will have no effect on reinforcement.

## Efficacy of Delayed Reinforcement

The ability to continue engaging in behaviors that are maintained by delayed reinforcement is often difficult. Organisms are more likely to engage in

immediately reinforced behaviors than behaviors that are reinforced after a delay period. For example, many individuals struggle to not eat the last piece of pie (immediate reinforcement) despite knowing the health benefits of refraining from doing so (delayed reinforcement). The ability to choose long-term benefits over short-term benefits is directly related to the concept of *delay discounting* (Mazur 2013). Delay discounting is the tendency to devalue a reinforcer as the delay of obtaining it increases, thereby leading individuals to place greater emphasis on smaller immediate reinforcers (a piece of pie) over larger delayed reinforcers (health). Delay discounting is an important concept for understanding self-control in humans because it points to the propensity for immediate rewards (piece of pie) over those delayed rewards that often take time to obtain (a healthy lifestyle).

To further understand delay discounting, it is important to understand how preferences toward immediate rewards over larger delayed reinforcers shift as a function of time. For instance, let's assume that a sweepstakes provides the option of choosing between a lump sum of \$10,000 in a year or choosing \$5,000 now. The choice of waiting a year for the \$10,000 seems like a much more lucrative option. Now imagine that instead of \$5,000 now, the sweepstakes provides the option of choosing between a lump sum of \$10,000 in a year or choosing \$8,500 now. The preference of originally waiting a year (larger delayed reinforcer) for the \$10,000 has now shifted to perhaps accepting the \$8,500 now (immediate reinforcer). This is what is referred to as the indifference point. An *indifference point* is when the delay and the amount/value of the reinforcer are considered equally preferable; in this example that point is the \$8,500. This can result in the preference switching between the two options; thus, there are moments when the same individual may actually choose the larger delayed reinforcer (health) over the immediate reward (piece of pie), but there are also moments when the reverse is true.

The *Ainslie-Rachlin Theory* explains how the value of a reinforcer is discounted as a function of the amount of time that passes between the choice

and receipt of the reinforcer (Ainslie 1975; Rachlin 1974). Specifically, the first assumption of the theory indicates that as the delay between making the choice and receiving the reinforcer increases, the value of the reinforcer decreases. The second assumption states that, at decision time, the reinforcer with the *highest* value will always be chosen. Therefore, despite the high value of a larger reinforcer (health), the delay of the reinforcer ultimately reduces the value that one places on their health. Moreover, when the individual is required to make a choice, the value of the piece of pie (immediate reinforcer) has significantly increased because of its close proximity. In the end, the piece of pie is considered greater than that of the healthy lifestyle. This line of research has helped explain impulsive choices that are often tied to maladaptive behaviors, such as drug/alcohol addiction.

The efficacy of delayed reinforcement depends on a variety of factors. Delayed reinforcement can decrease a behavior, increase a behavior, or leave the response rate unchanged. One factor that impacts its effectiveness is the purpose of delayed reinforcement. Delayed reinforcement is *primarily* used to maintain a response, also known as *response persistence* or *response maintenance* (Lattal 2010). Most studies involving delay of reinforcement examine the effects of the delay on response persistence, whereby a steady response rate was initially obtained via a schedule of immediate reinforcement. Another possible aim of delayed reinforcement is *response acquisition*. Here, delayed reinforcement is used to foster a response despite the absence of a learning history.

The length of the delay period preceding the presentation of the reinforcer is another factor that influences the efficacy of delayed reinforcement. In examining response acquisition, Skinner (1953) found that he was not able to condition a pigeon to peck a key with a 10-s delay preceding reinforcement, but he was able to do so with immediate reinforcement or a 1-s delay. This suggests that reinforcement following a 1-s delay was able to change a pigeon's behavior, but a 10-s delay was too long. Despite Skinner's observation, Lattal and Gleeson (1990) found that they

were able to shape rats' and pigeons' behaviors using a 30-s delay. Since then, the study has been replicated several times and has expanded to include different species, including humans. These works are important, as they demonstrate that delayed reinforcement can lead to response acquisition, even if it generally occurs at a slower rate than immediate reinforcement. In fact, a 0.5-s delay of reinforcement leads to higher rates of responding than immediate reinforcement. The ability to wait for a delayed reinforcement is very adaptive and useful for a species.

In terms of response maintenance, several studies have shown that as the delay of reinforcement increases (say from 1 to 10 s), the response rate decreases. An organism is less likely to perform the behavior that produces reinforcement when there is a larger delay preceding reinforcement. In addition, studies have repeatedly found that delay of reinforcement following a steady response engendered by immediate reinforcement produces a lower response rate than if the behavior was maintained by immediate reinforcement. In other words, while delay of reinforcement can maintain behavior, it is likely to result in a lower response rate. It is also important to understand that an increase in the delay of reinforcement will produce more variation in responding, potentially interacting with the existing contingencies.

Signaled and unsignaled delays also affect the efficacy of delay of reinforcement. While unsignaled and signaled delays are both likely to result in response acquisition and persistence, signaled delays maintain a higher rate of responding; however, the response rates are still lower compared to immediate reinforcement. Similarly, resetting delays are more likely to lead to response acquisition than nonresetting delays, albeit at a lower response rate than immediate reinforcement.

## Conclusion

As mentioned above, there are two main functions of delayed reinforcement: response maintenance or response acquisition. The primary function of delayed reinforcement is response maintenance:

to perpetuate a previously established behavior. Delayed reinforcement for this purpose is most commonly used when the response was previously established by immediate reinforcement. Contrary to previous beliefs, recent research has demonstrated that delayed reinforcement can also lead to response acquisition with a delay period as long as 30 s. In fact, 0.5-s delay was found to consistently produce higher rates of responding than immediate reinforcement.

Skinner and Thorndike were two of the first researchers to explore reinforcement. They believed that the behavior must be “closely followed by” the reinforcer in order for the behavior to be acquired. Although much research has been conducted on delayed reinforcement, it is still unclear how the phrase “followed closely by” should be operationalized. Part of the challenge lies in the dynamic relationships of the parameters of delayed reinforcement. The effect of delayed reinforcement on response acquisition and response maintenance varies with the different combinations of parameters. Current research is focusing on how to better predict the interactions of the parameters.

## Delayed Gratification

Molly Flessert<sup>1</sup> and Michael J. Beran<sup>2</sup>

<sup>1</sup>Georgia State University, Atlanta, GA, USA

<sup>2</sup>Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

Delayed gratification, a form of self-control, is defined as the ability to tolerate longer delays in order to obtain a more preferred reward as opposed to a more immediate, lesser preferred reward. Humans and nonhuman animals must weigh the costs and benefits associated with immediacy or delayed action in several contexts such as mate choice, food retrieval, and environmental conditions in which they live (e.g., Stevens et al. 2011). The uncertainty of the future may play an important role in choices to delay gratification or not. For example, how confident

someone may be that a more productive food source will be available in the future may directly affect whether that individual stays or moves on from the current food source. Delayed gratification also is crucial in contexts regarding planning for the future and goal-oriented behavior. For example, in an economic context, individuals must inhibit impulsive buying behaviors in order to save money for future purchases. For all of these reasons, understanding the psychological mechanisms that support delayed gratification has been a goal of developmental and comparative psychology.

Early developmental work on children's ability to delay gratification focused on whether children could abstain from taking a less preferred food reward in order to obtain a more preferred reward. In these tests, children usually were given a smaller reward such as one marshmallow, and told that they could eat that, but if they waited, they would get another marshmallow. This work demonstrated that preschool-aged children often were able to wait surprisingly long amounts of time, sometimes over an hour, in order to obtain a preferred reward. In other cases, delay was much shorter, showing that there was great variability across children, and also across testing contexts (e.g., Mischel and Ebbsen 1970; Mischel et al. 1972). Thus, the basic paradigm was one of inhibiting immediate consumption to gain a better, future reward. Extensions of this approach demonstrated that the ability to delay gratification is related to other self-control abilities and also to some degree with general intelligence (e.g., Duckworth et al. 2013).

The "marshmallow test" and other similar approaches in developmental psychology drew attention from those working with animal models of self-control behavior. Traditionally, animal models focused more on intertemporal choice tasks, in which animals such as pigeons chose between a smaller-sooner reward and a larger-later reward, with the latter choices then leading to a forced delay, rather than the need to continuously inhibit taking a reward (as in the marshmallow test). Pigeons typically showed strong discounting of the future, with heavy biases to take the smaller-sooner rewards. However, when

given a task in which they could peck to end a trial with a lower preference reward (like taking the one marshmallow) or avoid pecking to get a larger reward (the equivalent of the two marshmallows), pigeons showed many of the same environmental effects as children regarding how long they could delay, such as presence versus absence of rewards, having access to alternative responses, and having other stimuli present (Grosch and Neuringer 1981). Other approaches to making animal-friendly delayed gratification tasks involved having chimpanzees sit in front of one reward, which they could receive if they pressed a button, but if they waited, another reward would come later. In this test, chimpanzees avoided pressing the button when the lower preference food was the immediate reward, although they pressed the button immediately when the higher preference food was the one they could have immediately for such responding (Beran et al. 1999). These results, and others, led the way to the development of other tests of delayed gratification with animals (see Beran 2018).

Delayed gratification often has been studied in nonhuman animals using two approaches. The first involves having participants make a discrete choice between two rewards: one less preferred, yet more immediate, and one more preferred, yet more delayed. This intertemporal choice paradigm allows for a commitment to a higher, delayed payoff, because choice of the delayed reward forces the participant to experience the full delay (e.g., Addessi et al. 2011; Amici et al. 2008; Rosati et al. 2007; Stevens et al. 2005). Alternatively, tests can involve an aspect of having to continuously maintain a commitment to delaying gratification because participants can still choose the immediate reward or they can choose to continue to delay gratification. In this approach, subjects can stop waiting for the better reward at any point in time, resulting in varying amounts of final reward given how long they maintain that delay.

One of these latter tests is known as the accumulation test (Beran 2002). It was based on another developmental design (e.g., Toner and Smith 1977) in which children postponed gratification during a period in which they observed

rewards growing over time. The novelty of this approach was that, unlike the marshmallow task, in which delayed gratification occurred in the presence of only a static, immediate reward, in the accumulation test the immediate reward gets better over time. In this kind of test, the possibility of that reward continuing to get better is predicated on the subject not giving in and taking the accumulating reward. Toner and Smith (1977) showed children between 33 and 120 months old that M&M's candies would be placed one by one on the table in front of them until the child instructed the experimenter to stop and they could receive the candies. This design lends itself nicely to comparative work, because it does not necessarily require any verbal instruction and can be presented in an intuitive fashion to a variety of species. The first use of this task was with chimpanzees and an orangutan (Beran 2002), in which they too watched as M&M's candies accumulated in a bowl that was within reach. As long as they waited, more would be added, but taking and eating any items ended the trial. These apes were able to wait to get all of the items that could accumulate, and other studies also showed that great apes can successfully delay gratification in order to receive the higher amounts of reward following a period of accumulation (e.g., Parrish et al. 2014; Stevens et al. 2011). Additionally, recent research shows that, similar to humans, delay of gratification in chimpanzees is closely linked to their general intelligence (Beran and Hopkins 2018).

The accumulation task can be adapted in a number of ways to ask questions about environmental factors that might impact delayed gratification. For example, visibility of rewards makes a big difference for children. Similar tests with chimpanzees manipulated the visibility of the reward source by obscuring the preferred reward from subjects' visual field. When chimpanzees were shown the quantity of rewards before visual access was blocked, they were still successful in delaying gratification (Beran and Evans 2006). Beran and Evans (2006) also reported that chimpanzees were successful even in the absence of a human experimenter as the agent of the ongoing accumulation. An automated dispenser that

delivered foods to the accumulation pile did not lead to decreased delay performance. In addition, chimpanzees were successful when the accumulation that occurred was not for immediate, real food rewards but instead was for tokens that could be traded for rewards at a later time (Beran and Evans 2012). This research demonstrated that in multiple variations of accumulation tasks, great apes have a high capacity for inhibiting impulses to receive an immediate reward in order to obtain a higher value or greater amount of reward.

Delaying gratification is about waiting to get something better. However, a lot of factors can impact how well one can do this. Successfully delaying gratification often includes engaging in behavioral tactics that aid in the waiting process or what is sometimes called *delay maintenance*. It is during delay maintenance that one can see the effects of environmental features interacting with strategic efforts by a subject. Some of those strategies are effective, and some are ineffective. One highly effective strategy involves directing attention away from the rewards through self-distraction. For example, children's ability to delay gratification is increased when the preferred reward is absent and therefore unattended to (Mischel and Ebbsen 1970), when distractions such as playing with a toy are available or when participants are encouraged to think about something positive or "fun" (e.g., Mischel et al. 1972). Delay is better when children verbally repeat phrases either irrelevant to the task or about the goodness of waiting (Toner and Smith 1977). These results all beg the question as to whether nonhuman animals also might engage in behavioral strategies to aid delay of gratification.

Mixed results on distraction tactics have been found in the comparative work with great apes. Early tests with the accumulation task in chimpanzees did not observe any changes in delay periods as a result of attending to the rewards or having the opportunity to distract themselves with a computerized task (Beran 2002; Beran and Evans 2009). Similarly, behaviors that either directed attention to or away from the delayed reward (such as self-grooming or touching the bowl in front of them, respectively) resulted in no difference in ability to maintain delay (Beran

and Evans 2006). However, when toys were made available as a distraction tool, chimpanzees tended to wait longer periods of time before ending accumulation of candy rewards, and the results highlighted a special aspect of what the chimpanzees were doing (Evans and Beran 2007a). Whereas it was true that chimpanzees waited longer when they had toys compared to when they did not, this was not, in itself, evidence of strategic self-distraction. What was more convincing was a comparison of two conditions, both of which involved toys being available. However, the difference was that in one condition, the accumulating food rewards were within reach of the chimpanzees, and thus they had to leave those food items alone if more were to accumulate. In the other condition, food rewards still accumulated in view of the chimpanzee, but they were out of reach, and thus the chimpanzees did not have to show delayed gratification. Despite toys always being available in these two conditions, the chimpanzees played with the toys for more time when they were in the delayed gratification condition, suggesting that they selectively used the toys for those trials where they had to maintain delay versus a condition where the delay was imposed upon them. This study suggested that humans are not the only species to distract themselves from the task at hand in order to aid in impulse inhibition. Other research (reviewed below) would also support this contention.

Comparative work with nonhuman primates also has explored the ability of monkeys to delay gratification. While some species have shown varying degrees of success, such success typically is less than that seen in great apes. In an accumulation task like that described earlier with consistent transfer of items, only three of nine Rhesus macaques consistently maintained delay of gratification. However, seven of those nine monkeys showed increased delay of gratification when the accumulation task introduced reward inequalities and high-preference rewards were presented last in the accumulation (Evans and Beran 2007b). Capuchin monkeys and squirrel monkeys also were only able to maintain delay when accumulating food items increased in size or with large

amounts of experience in the task (Anderson et al. 2010), and in this case only two of four capuchin monkeys and two of four squirrel monkeys demonstrated this ability for delay periods of only 1–5 s. However, in another experiment, capuchin monkeys showed no improvement over time on a discrete choice test between smaller-sooner and larger-later rewards, but evidence of improvement was found for several monkeys in an accumulation task (Addessi et al. 2013). This result not only shows the variability in performance across tasks as well as between individuals but also calls into question the equivalence of self-control measures that are often taken to be interchangeable. A nice example of this comes from research with rats in which animals engaged in either a delay discounting task, where the smaller-sooner and larger-later reward choices were adjusted but choice of the delayed reward led to automatic delay periods, or a delay of gratification task where choice of the larger reward was something the rats could “bail out” of during the delay. This study found no significant relation among rats in the rates of discounting delay (making an irreversible choice to delay) and delay gratification (maintaining a choice to delay without defecting; Reynolds et al. 2002). Such results have important implications for understanding how consistently different tasks, that should reflect a common self-control capacity, actually do so.

Evans et al. (2012) tested capuchin monkeys and chimpanzees on a task in which the accumulating items were tokens instead of actual food items. This task required the animals to learn the meaning of the tokens as they related to actual food rewards. The question was whether monkeys and apes exhibited similar levels of self-control when non-food rewards accumulated versus actual food rewards. If they understood that tokens represent amounts of reward they could receive, their ability to delay gratification for tokens should match their performance on tasks in which food items accumulate. However, capuchin monkeys accumulated significantly fewer tokens than food items, indicating that they struggled to generalize the value of symbolic items to the value of a food reward. Chimpanzees,

however, were able to accumulate items regardless of whether or not the items were tokens or food items. The results of this study highlighted an important difference between great apes and monkeys, in that apes more easily recognized the value of tokens in accumulating delayed rewards.

Another widely used approach to assessing delay of gratification in animals involves exchange tasks, which also highlight species differences in nonhuman primates' ability to initiate and maintain delays. In exchange tasks, animals must willingly trade items in their possession to obtain more preferred rewards, and thus necessarily delay gratification. This involves the choice to initiate a delay and also the ability to physically give up the immediate reward as part of a trade. Chimpanzees, long-tailed macaques, Tonkean macaques, brown capuchins, and domestic dogs are among those who have demonstrated successful delay maintenance in exchange tasks (e.g., Beran et al. 2016; Dufour et al. 2007; Pelé et al. 2010, 2011; Leonardi et al. 2012). These experiments, like the accumulation task, also have demonstrated the effects of varying the delay duration, the quantity of delayed reward, and the quality of delayed reward. For example, Pelé et al. (2010, 2011) reported that when they allowed monkeys the option to immediately trade their food items (rather than having to constantly inhibit their impulses to eat available food by holding onto food until the chance to exchange came), delay periods increased from just seconds up to 20 min for capuchins and about 40 min for rhesus macaques. This astonishing increase in delay maintenance highlights how large a role consumption inhibition plays in monkeys' ability to maintain delay. When they must hold on to a reward and restrain themselves from eating it, it is substantially harder to delay gratification as opposed to when they can immediately trade the food and no longer have the option to consume it. Pelé et al. (2010, 2011) also compared monkeys' delay periods in the exchange task to their subsequent performance on an accumulation task. This showed that monkeys typically delayed reward in the accumulation task for time periods similar to those for the exchange task (in which

subjects had to wait before they traded), despite the quantity of final rewards being substantially smaller in the accumulation task. In other words, monkeys chose to delay for similar periods of time given varying amounts of their final reward. There were also individual and species differences, indicating that capuchins did not maintain delay periods and inhibit impulsivity for as long as macaque species.

When tested with a similar exchange paradigm, 2-year-old children were unable to wait longer periods for larger rewards, but 3- and 4-year-old children could. All children were able to increase their initial delay periods when the final reward was much larger than the reward they initially were given (Steelandt et al. 2012). Here, older children were also able to anticipate longer delay periods with smaller rewards, choosing to end those delay periods sooner. This reflected their ability to weigh the costs and benefits given the length of delay and size of reward, which has also been demonstrated in chimpanzees and rhesus monkeys (Dufour et al. 2007; Pelé et al. 2010, 2011).

Although much of the research on animal delayed gratification has been conducted with nonhuman primates, other species have been studied. More recent efforts have focused on the ability of bird species to inhibit impulsivity. Specifically, corvids (including ravens and crows) were more likely to delay gratification when the preferred reward involved a higher quality food item than a higher quantity of the immediate, lesser-preferred reward (Hillemann et al. 2014). Similar to results from nonhuman primates, these results indicate that some birds delay gratification and resist impulsivity for an immediate reward. Similarly, a Grey parrot was able to maintain delay of gratification both when the less preferred, more immediate reward was within reach or was out of sight (Koepke et al. 2015). However, this study differed from the comparative research described earlier, in that this parrot was language trained and was specifically told the command to "wait" and not eat the immediate reward in return for a preferred reward. During a different accumulation task with other

Grey parrots, birds displayed limited levels of delayed gratification. Those individuals were unable to obtain the maximum number of rewards (five) and showed little to no improvement over the course of 30 test trials (Vick et al. 2010). These tests, like those given to nonhuman primates, highlight the importance of different testing paradigms and other factors such as rearing conditions when testing certain nonhuman species. Additionally, this research with non-primate species underscores the importance of testing a broad range of species in order to better understand how individual differences and species' characteristics may impact delay of gratification and other forms of self-control.

Overall, comparative research investigating nonhuman animals' delay of gratification provides promising evidence that animals can indeed endure long periods of delay in return for a larger reward payoff. This evidence contradicts past notions that only humans possessed these abilities. The impressive levels at which great apes can delay gratification draws clear evolutionary connections between humans and our great ape cousins. But, the success of monkeys and of non-primate species in some tasks shows that delayed gratification is a capacity widespread in the animal kingdom, even if it is often limited and fallible in some contexts. Like humans, animals have complex lives that require complex cognitive skills. It is critical for survival to make well-informed decisions, some of which involve waiting for longer periods of time for a better reward of some type – whether that is access to better food, better chances to mate, or increased safety by avoiding predators. Research investigating humans' and animals' abilities to inhibit impulsivity and show delayed gratification continues to increase our understanding of the similarities and differences of human and animal cognition and behavior.

## Procedure

The delayed match-to-sample procedure (commonly abbreviated as DMTS) is a modification of the basic match-to-sample procedure (also known as match-from-sample and choice-from-

sample), which was first used as early as 1799 (see Weinstein 1941). With the match-to-sample procedure, the subject is presented with a visual sample stimulus and is then also presented with two or more additional comparison stimuli, one of which matches the original stimulus. The subject must then choose the comparison stimulus that matches the original sample stimulus. The subject is usually rewarded for correct matches. With the DMTS procedure, the sample stimulus and comparison stimuli are not presented simultaneously. Instead, there is a delay between the removal of the sample stimulus and the appearance of the comparison stimuli. To begin, the subject is first shown the original sample stimulus for a specified amount of time or until the sample is touched or otherwise responded to by the subject, and then the sample stimulus is removed. After a delay lasting a predetermined amount of time, usually seconds or minutes, the subject is presented with two or more additional comparison visual stimuli, one of which matches the original sample stimulus. The subject must then choose the comparison stimulus that matches the original sample stimulus. For example, imagine the subject is shown an image of a circle for 3 s, after which time, the image is removed followed by a 10-s delay. Next, the subject is shown two comparison stimuli, a circle and a triangle. In this case, the matching comparison stimulus would be the circle, as it matches the sample stimulus.

This procedure, as well as the basic match-to-sample procedure, is commonly used in cognitive research with humans and animals to investigate topics relating to learning and memory. The delayed match-to-sample procedure can also be used as a tool to investigate more complex phenomenon such as perception of the passage of time (Zentall and Smith 2016) or as a measure of cognitive function (Kangas et al. 2011). One advantage of these procedures is that they can be conducted without the use of language, making them ideal for studies involving animals (Zentall and Smith 2016) and human infants (Hochmann et al. 2016). However, both procedures depend on the subject's ability to understand or learn the concepts of same and/or different (Hochmann et al. 2016). The delayed match-to-sample

procedure also requires the use of memory, as the subject must be capable of remembering, either consciously or unconsciously, the original sample stimulus after it is no longer visible.

## Variations

The simplest form of matching, known as identity matching, requires the subject to identify the comparison stimuli that is an exact match to the sample, but there are other forms of matching as well. Instead of an exact match, the stimuli may conceptually match the sample in a variety of ways including color, size, number, form, function, symbolic relationship, or any other possible association. Thus, the delayed match-to-sample procedure can be used to investigate topics such as concept formation (Zentall and Smith 2016). For example, if the sample stimulus was a red circle and the comparison stimuli were a blue circle and a green triangle, the matching comparison stimulus would be the blue circle because, even though the colors do not match, they are the same shape (Vonk 2003). A more advanced example would be if the sample stimulus was a hammer and the comparison stimuli were a saw and a tree. In this case the matching comparison stimulus would be the saw, as the hammer and saw are both tools. One modification of this task is the delayed non-match-to-sample (DNMTS) task in which the subject is reinforced for choosing the comparison stimulus that does not match the original sample stimulus (oddity). Various other modifications of this procedure can be made to investigate other aspects of memory and cognition.

## Delboeuf Concentric Circles

### ► Delboeuf Illusion

## Delboeuf Illusion

Audrey E. Parrish  
Department of Psychology, The Citadel,  
Charleston, SC, USA

## Synonyms

Delboeuf concentric circles; Geometric illusion;  
Size illusion

## Definition

The Delboeuf illusion is a geometric visual illusion that emerges when the size of a central dot is misperceived as a function of the diameter of a concentric ring that encircles the dot. A larger outer ring leads to underestimation of central dot size relative to a smaller outer ring which leads to overestimation of central dot size. The Delboeuf

illusion is similar to the well-known Ebbinghaus-Titchener illusion in which central dot size is misperceived as a function of contrast and assimilation mechanisms. The Delboeuf illusion has been studied extensively within the human literature and recently has been extended to a variety of animal species.

## The Delboeuf Illusion

The Delboeuf illusion emerges when the size of a central target dot is overestimated if encircled by a small concentric ring and, alternatively, underestimated if encircled by a relatively larger concentric ring (Fig. 1). Joseph Delboeuf, a trained experimental psychologist, mathematician, and philosopher, first documented this size illusion in the late 1800s amidst a boom of experimental reports on related geometric visual illusions. Our current understanding of the phenomenon is posited by the assimilation-contrast theory in which the central dot is contrasted against the larger concentric ring due to the increased distance between the dot and the ring, leading to underestimates of dot size. Alternatively, the smaller concentric ring is perceptually integrated with the central target dot due to the close spatial proximity of the dot and the ring, leading to overestimates of dot size. The Delboeuf illusion, similar to other misperceptions of size such as the Ebbinghaus-Titchener illusion (Fig. 1), more readily emerges when the target dot and concentric ring are holistically (or globally) processed such that the stimuli are perceived simultaneously.

Visual illusions, in general, provide an excellent tool for investigating the perceptual systems of a wide range of species via noninvasive testing procedures. Whether a given species (or specific individuals within a species) experience geometric size illusions highlights important similarities and differences in sensitivity to contrast and assimilation effects as well as perceptual processing mode. Perceptual processing mode refers to whether an individual first perceives the global configuration of a stimulus array (e.g., dot plus ring) or the individual elements that comprise the

**Delboeuf Illusion, Fig. 1** The Delboeuf illusion (a) and Ebbinghaus-Titchener illusion (b), in which central dot size is underestimated when encircled by larger inducers

(at left) and overestimated when encircled by smaller inducers (at right). (Adapted from Parrish et al. 2015)

figure (e.g., dot then ring, or vice versa). Perceptual processing varies across species with some demonstrating a human-like global-to-local precedence and others demonstrating a local-to-global precedence. For example, a global-to-local precedence would lead to the simultaneous or global processing of the concentric ring plus central dot as a single unit, whereas a local-to-global precedence would lead to the individuation of ring and dot prior to processing its global configuration. Whether individuals process the Delboeuf array globally (along with other multi-element arrays) also is a by-product of stimuli presentation. Methods that enhance the individual features of the array as separate units (i.e., via different color cues – black dot, red ring – or presentation style, sequential presentation of dot then ring) may disrupt global processing, which is fundamental to the emergence of illusory perception.

A variety of testing paradigms are employed to investigate sensitivity to visual illusions, including the spontaneous choice task (also known as a free choice test) which requires animals to select the larger of two food quantities. This paradigm requires little to no training as it mimics a naturalistic choice setting in which animals are typically motivated to maximize by selecting the largest or highest-quality food set available. Foods are arranged to reflect the illusory arrays to test for perceptual sensitivity of the illusion under investigation. To dissociate the role of motivation and to carefully control for external cues and stimulus design, visual illusions also are presented using two-dimensional stimuli. The stimuli (e.g., black

and white renderings of illusory arrays) are presented either manually or via computerized testing. Animals are trained to select the larger or smaller of two stimuli (a relative discrimination task) or are trained to classify a single stimulus as large or small relative to a predetermined criterion (an absolute classification task). Stimuli are presented using the illusory-inducing context (e.g., central dot plus illusory ring) to determine whether subjects are sensitive to the illusion once trained on the task parameters (via reinforcement for correct responding). Comparative results have led to interesting similarities and differences in perception of the Delboeuf illusion using these paradigms, shedding light on continuities and divergences in perceptual mechanisms, quantity estimation abilities, and the role of methodology in assessing visual illusions.

### Comparative Assessments of the Delboeuf Illusion

The Delboeuf illusion has been studied extensively in the human literature, primarily using two-dimensional stimuli as described above. The impact of this geometric size illusion on choice behavior in the consumer domain also has been explored. The Delboeuf illusion appears to impact real-world decision-making scenarios including food judgments and consumption behavior. In a study with human adults, participants misjudged food portions (mimicking the central Delboeuf dot) as a function of the dishware (mimicking the outer ring) on which they were served.

Participants routinely overestimated food portions plated on smaller dishes and underestimated food portions plated on larger dishes akin to the illusory effect when judging two-dimensional dots encircled by rings (e.g., Van Ittersum and Wansink 2012). Misperceiving food portions has obvious implications for consumption behavior, with an increase in calorie intake as a function of plate size and portion estimation.

In the first study to assess the Delboeuf illusion among animals, Parrish and Beran (2014) employed the spontaneous choice task featuring edible stimuli to assess how this visual illusion may impact food choice behavior among chimpanzees (*Pan troglodytes*). Chimpanzees first were presented with control trials that pitted two different quantities of food against one another when both food portions were plated on the same-sized dishes (either both on small plates or both on large plates). A critical first step in utilizing the spontaneous choice task to assess illusory perception is to demonstrate proficiency in control trials with a true difference in food quantities presented in a non-illusory inducing context (in the case of the Delboeuf illusion, on same-sized plates). Failure to maximize in control trials may reflect low motivation or the inability to discriminate quantities at a given ratio, which may be necessary to perceive the illusion under investigation in critical test trials. Thus, the ability to reliably and effectively discriminate the size of central target dots (or food portions) in the absence of the illusory context is a pre-requisite for assessing the emergence of the Delboeuf and other size illusions.

In the spontaneous choice task, chimpanzees excelled in control trials, selecting the larger of two food portions when presented on same-sized plates (Parrish and Beran 2014). Similar to misperceptions made by humans, chimpanzees preferred food portions presented on a small plate to an equal-sized food portion plated on a larger plate. Thus, objects with a small surround appeared to be perceived as larger than the same-sized object with a large surround, in line with the Delboeuf illusion. Some chimpanzees also erroneously selected a smaller food portion on a small plate relative to a larger food portion on a large

plate, leading to the consumption of an overall smaller amount of food. These results are striking in that chimpanzees, who are highly proficient in discriminating very small differences in food amounts, performed sub-optimally in terms of maximizing the amount of preferred foods in illusion trials that they chose and ultimately consumed. This occurred for different food types and across repeated trials, and for animals that were highly motivated to maximize in spontaneous choice tasks of this nature, suggesting continuity in perception of the Delboeuf illusion across species.

Several other animal species have been presented with the Delboeuf illusion using the spontaneous choice paradigm. Positive evidence for the illusion has been documented in a variety of taxa, including domestic cats (*Felis silvestris catus*: Szenczi et al. 2019), bearded dragons (*Pogona vitticeps*: Santacà et al. 2019), and damselfish (*Chromis chromis*: Fuss and Schluessel 2017), which also fall prey to the highly similar Ebbinghaus-Titchener illusion (Fuss and Schluessel 2017). Alternatively, lemurs (*Lemur catta*) were not sensitive to the Delboeuf illusion using the spontaneous choice task, showing indifference in illusion trials with equal likelihood to select food presented on a large or small plate. It is important to note that the lemurs did not reliably discriminate food portions during control trials, suggesting that they may have failed to discriminate quantities at a given ratio necessary to perceive the Delboeuf illusion (Santacà et al. 2017). A similar finding was reported for red-footed tortoises (*Chelonoidis carbonaria*) who also failed to maximize in control trials, limiting the interpretation of illusory performance (Santacà et al. 2019).

Domestic dogs (*Canis familiaris*) have been reported to show no sensitivity to the Delboeuf illusion using the spontaneous choice task (Miletto Petrazzini et al. 2017) and have even demonstrated reversed perception of the Delboeuf illusion when judging two-dimensional stimuli (Byosiére et al. 2017). Bamboo sharks (*Chiloscyllium griseum*: Fuss and Schluessel 2017) and guppies (*Poecilia reticulata*: Lucon-Xiccato et al. 2019) also perceived a reversed Delboeuf illusion. Male guppies have dots located

on their body flanks that vary in size and coloration that are sometimes encircled by an outer ring, making this species an interesting subject for Delboeuf studies. In Lucon-Xiccato et al.'s (2019) study, guppies successfully learned to approach the larger of two orange dots suspended in their fish tank for a variety of ratios in control trials. However, they did not show evidence for the Delboeuf illusion when the dots were encircled by an outer ring. When presented with the spontaneous food-choice task, guppies again performed well in the control trials, yet preferred food encircled by a large ring versus a small ring (i.e., a reversed illusion). These results are interesting in light of the positive evidence for a human-like susceptibility to the Delboeuf illusion and the highly similar Ebbinghaus-Titchener illusion by other teleost fish (e.g., damselfish: Fuss and Schluessel 2017). Guppies may be more sensitive to assimilation effects which could lead to a reversed illusion in that the ring, regardless of its size, would be incorporated with the dot leading to overestimates (rather than underestimates) of dot size when encircled by large rings.

Such discrepancy in perception of the Delboeuf is not uncommon for geometric visual illusions, which often emerge variably across species and even produce high rates of individual differences within the same species. In addition to quantity discrimination abilities and perceptual processing mode, the methodological procedures for presenting illusions to subjects play a critical role in their emergence. When presented with a computerized version of the Delboeuf illusion, capuchin monkeys and rhesus monkeys demonstrated proficiency in discriminating a range of central dot diameters in control trials using the relative discrimination task (i.e., select the larger of two central dots encircled by the same-sized rings or in the absence of rings; Parrish et al. 2015). However, a number of monkeys from both species perceived the Delboeuf illusion in a reversed manner as described above for guppies (Lucon-Xiccato et al. 2019) and some individual dogs (Byosiére et al. 2017). However, when presented with an absolute classification task, both species of monkeys performed similarly to human adults completing the same task – overestimating

the central dot as a function of outer ring size, such that progressively smaller rings led to progressively greater overestimates in perceived central dot size. These results underscore the effects of methodology – the large-ring bias that led to a reversed illusion in the first experiment using the relative discrimination task may have reflected a bias to selecting the larger overall array (central dot + outer ring) versus discriminating on the basis of the central dot only. The absolute classification task was an important contrast within this study as it potentially reduced attention to either element in the array (dot or ring), instead presenting a range of the central dots and outer rings at equal rates throughout training and testing. This is particularly important for locally oriented species including capuchin monkeys and rhesus macaques, as a local-to-global precedence results in the initial perception of individual elements that comprise an array (dot and ring, for the Delboeuf array) prior to holistic processing, which may reduce sensitivity to geometric illusions. These results highlight the interconnectedness of species' perceptual processing mode and the methods used to investigate illusory phenomena.

## Summary

Assessing whether nonhuman animals perceive visual illusions provides a unique means for establishing similarities and differences in the perceptual and visual systems of a variety of species. Geometric size illusions in particular have played an important role in the history of comparative psychology and perception studies, with an increasing breadth of species and illusory arrays under investigation. The Delboeuf illusion and the related Ebbinghaus-Titchener illusion have attracted particular attention in that they result in interesting differences both within and across species. Null results and evidence of reversed patterns of illusory perception may reflect true differences in the perceptual experiences of animals and various populations. Such variability may stem from differences in perceptual processing mode, quantity discrimination abilities,

or sensitivity to contrast and assimilation mechanisms. It also is important to develop tests that allow for full exploration of these issues while parsing out the role of methodology (e.g., stimulus design, presentation, training procedures, reinforcement contingencies, etc.) in the emergence (or not) of illusory experiences. The Delboeuf illusion has proven to be an important tool to explore these issues in comparative psychology.

## Synonyms

[Dendrons](#); [Nerve fiber](#)

## Definition

Dendrites are branched fibers that stem from the cell body (soma) of a neuron.

## Introduction

The dendrite was first discovered by Swiss anatomist Wilhelm His (Mall 1905). He's made the discovery in 1889 when he coined the term dendrite to refer to the "protoplasmic processes" connected to a neuron. From this initial discovery, we now understand that dendrites are branched fibers that stem from the cell body (soma) of a neuron. Dendrites receive electrochemical messages, usually in the form of neurotransmitters, from other neurons via specialized receptors

located on the surface of the dendrite (Urbanska et al. 2008). When the dendritic receptors receive the electrochemical messages from other nerve cells, the cell membrane of the neuron will passively change in polarity, dependent on the nature of the neurotransmitters received. The polarity change will move from the dendrites toward the axon. If an action potential is not reached, which would generally be due to the dendritic receptors receiving more inhibitory neurotransmitters than excitatory, the neuron will not fire, and the electrochemical message will end (Barnett and Larkman 2007). If an action potential is reached, however, the electrical message will be sent from the dendrite, through the axon hillock, down the axon, and to the terminal button. At the terminal button, the electrical message will change into a chemical message, whereby exocytosis will occur and neurotransmitters will be released into the synapse between the presynaptic and postsynaptic neuron. Once released into the synapse, the released neurotransmitters will potentially connect to the receptors on the dendrites of the postsynaptic neuron, starting the electrical stimulation paradigm over again (Barnett and Larkman 2007).

The amount of electrochemical messages a dendrite can receive is dependent upon its surface area and the number of receptors located on the dendrite (Tvonsanis 2012). In general, the larger the surface area of the structure, the more messages the dendrite can receive from other neurons. The shape of the neuron can influence the surface area available for the reception of electrochemical messages. There are three main types of neuronal shapes: multipolar, bipolar, and unipolar. Multipolar neurons consist of one axon and many branches of dendrites. Bipolar neurons have one axon and dendritic trees at both ends of the axon. Unipolar neurons have an axon that separates into two ends, one that has dendrites and the other that contains terminal buttons. The different types of neurons are responsible for different behaviors. Dendritic spines, projections that extend from the base dendritic structure of all neurons, can increase the surface area of the dendrites. The growth of dendrites is called dendritic branching which is a process that allows nerve cells to make new dendritic trees which in turn creates new

synapses with surrounding neurons (Tvonsanis 2012).

Initially, however, it was believed that dendrites could not change and that their structure was set by the adolescence of the organism. This, however, has been countered with the idea that dendrites do, indeed, have a certain amount of plasticity, specifically in the branches and dendritic spines (Koleske 2013). This changeability of the dendrites is linked to learning, as it is believed that experiences guide the growth of neurons (Yang et al. 2009). Neuronal experiences equate to increased neural stimulation. The more stimulation a dendrite receives from other neurons, the more growth will occur, even in species other than humans (Coss et al. 1980). An experience such as learning causes the stimulation of neurons and the creation of stronger synaptic connections between pre- and postsynaptic neurons. This increased stimulation can occur due to the induction of the process known as long-term potentiation (LTP). The ability of the organism to engage in LTP is linked to learning and memory formation and the subsequent growth of dendrites (Sjöström et al. 2008).

## Conclusion

Dendrites are a part of the neuron that have many responsibilities such as receiving and propagating excitatory messages from presynaptic to postsynaptic neuron. They are attached to different shapes and types of neurons and are changeable based on the conditions they are in. When a dendrite is stimulated, it becomes plastic – it grows. When a dendrite grows, it creates new synapses with both new and old neurons which allows for additional electrochemical messaging to occur.

We know that learning and memory formation can lead to the growth of dendrites and the strengthening of synaptic connections. By understanding the role of the dendrite in learning and memory, we might be better able to not only realize how our brains work but also create paradigms to study new treatments for memory-related diseases such as Alzheimer's disease and other forms of dementia.

## Dental Formula

Kayla Alexander

College of Veterinary Medicine, Mississippi State University, Mississippi State, MS, USA

## Synonyms

[Deciduous teeth](#); [Dentition](#); [Permanent teeth](#); [Primary dentition](#); [Secondary dentition](#)

## Definition

(Dental formula) is an abridged expression for the number and kind of teeth of mammals... and the number in each jaw is written like a fraction .... (Merriam-Webster 2018)

Different species of mammals have different amounts of teeth, and therefore, different dental formulas. The dental formula has been developed to help practitioners easily and accurately express the number of and positions of animals' teeth. The dental formula will change over the life of an animal as it matures from adolescence into adulthood and the number of teeth change. Practitioners and scientists can use the dental formula of an animal, or animal remains, to determine age or to identify the species.

Primary dentition, also known as deciduous teeth, is the teeth mammals have during adolescence. Deciduous teeth will be shed as the animal grows and matures into adulthood (AVDC 2018).

In their place, permanent teeth, or secondary dentition, will grow. The number of deciduous teeth is less than the number of permanent teeth. This means the deciduous dental formula will consist of fewer teeth than the permanent dental formula for a given species.

Along with the dental formula, the types of teeth also vary between mammalian species. Animals that are carnivores (meat eaters) or omnivores (varied diet) have teeth that are adapted to perform specific functions in the process of obtaining and chewing food. Herbivores (plant eaters) have teeth that are more uniform in appearance and are adapted to eating plant material. Ruminant species (cattle, sheep, and goats) lack upper incisor teeth. Instead, these animals have a dental pad, which is modified, toughened skin, in the center of their upper jaw. Ruminants use their tongues to pull food into their mouths instead of biting plants with their front teeth. Equine species (horses, zebras, donkeys) and rodents have teeth that continually erupt throughout the life of the animal. They also have a gap between the front and back teeth known as a diastema (Easley 2018). These animals use either their lips (horses) or front paws (rodents) to pull food into their mouths and use mainly the back teeth for chewing.

There are four basic types of teeth in mammals. Each kind of tooth has developed to perform a certain function in the process of mastication (obtaining and chewing food). Below, the types of teeth and the corresponding function are described:

- Incisors are the teeth in the front of the mouth. They have developed to act like chisels or shovels. Incisors function mainly to bite off pieces or slabs of food into an appropriate size for chewing (Myers and Espinosa 2018).
  - The dental pad is a special structure in the mouths of ruminants that replaces the upper incisors. Ruminants use their tongue to hold food against the dental pad and bite the food into smaller pieces with their lower incisors (Hall and Silver 2009).
- Canine teeth are the sharp, pointed teeth just behind the incisors. These teeth are used to stab and hold food. Canine teeth may be exaggerated in size in some species as a form of social or sexual display.

- Premolar teeth are those in between the canine teeth and molars. Premolars vary from molars because they are present in the mouths of adolescent animals, whereas, molar teeth are not. Premolars function to crush food.
- Molar teeth are those in the very back of the mouth. Molars are the last teeth to erupt and are present only when an animal has reached adulthood. The molars perform the function of crushing and grinding food (Myers and Espinosa 2018).

The dental formula is written as a fraction, where the tooth on the top jaw is written over the corresponding tooth on the bottom jaw. However, only one half of the mouth is written, therefore, the values must be doubled to obtain the total number of teeth. The dog is used as an example to explain the process for writing a dental formula.

In the dog, there are 3 incisors on the upper jaw and 3 incisors on the lower jaw on each side of the mouth. Using the letter I to represent the incisors, the incisor teeth of the upper and lower jaw are noted as  $I_3^2$  in the dental formula. Next, the canine teeth are denoted with C. The dog has 1 upper and 1 lower canine on each side of the mouth. Therefore, the canine teeth are written as  $C_1^1$ . For the premolars (P), the dog has 4 upper and 4 lower, so they are written as  $P_4^4$ . For the canine molars (M), there are 3 upper and 2 lower and are written as  $M_3^2$ . The sections beginning at the midline of the mouth and moving towards the back of the mouth are strung together to construct the complete formula:  $(I_3^3C_1^1P_4^4M_3^2)$ . When denoting permanent or secondary teeth, the letters are capitalized. When denoting deciduous or primary teeth, the letters are lower case (Muyllle 2018). When representing a full mouth of teeth, the number two is placed in front of the formula, such as for the dog,  $2(I_3^3C_1^1P_4^4M_3^2)$ , to represent the entire mouth.

Some adult, or permanent, dental formulas for common domestic species are below (Muyllle 2018):

|       |                           |     |                           |
|-------|---------------------------|-----|---------------------------|
| Dog   | $2(I_3^3C_1^1P_4^4M_3^2)$ | Cow | $2(I_3^0C_1^0P_3^3M_3^3)$ |
| Cat   | $2(I_3^3C_1^1P_2^2M_1^1)$ | Pig | $2(I_3^3C_1^1P_4^4M_3^3)$ |
| Horse | $2(I_3^3C_1^1P_3^3M_3^3)$ |     |                           |

Image by David Crossley for the Royal Veterinary College, 2002

Another method to identify the teeth of mammals is the Modified Triadan Numbering System. The mouth is divided into four quadrants: a right and left side of each top and bottom jaw. A dividing line is drawn down the center between the two front incisors. Each quadrant is assigned a number series in a counterclockwise fashion. The upper right quadrant is assigned to the 100's. The upper left quadrant is assigned to the 200's. The bottom left quadrant is assigned to the 300's, and the bottom right quadrant is assigned the 400's. To specify a certain tooth within each quadrant, a predetermined number is added to the assigned 100 series number. The incisor immediately adjacent to the dividing middle line is tooth number 1, so the first incisor of the upper right quadrant is known as 100 (the quadrant number) + 1 (the tooth number) = 101. The teeth are noted in numerical order from the front incisor to the last molar. If there is a tooth missing, or a species naturally lacks a tooth in a particular position, the number is skipped or omitted. Two easy anatomical markers for numbering teeth are the canine and molar teeth. The canine tooth in a quadrant is always known as X04 (the upper left quadrant is 204; the bottom left quadrant is 304; etc...). The first molar is always known as X09

(the upper right quadrant is 109; bottom right quadrant is 409; etc...) (AVDC 2018) (Fig. 1).

The dental formula is a helpful tool in aging animals and identifying species of skeletal remains and fossils. By using an organized and widely accepted dental numbering system, scientists and practitioners are able to easily communicate information about the teeth of mammalian species. The dental formula and Modified Triadan Numbering System are important tools in the practice of veterinary medicine and the science of biology.

## Synonyms

Dentate fascia; Fascia dentata hippocampi; Gyrus dentatus

## Definition

It is the segment of the neocortex that constitutes a part of the hippocampal formation and is involved in crucial processes of learning, memory, and neurogenesis.

## Introduction

Dentate gyrus is composed of gray matter and makes an important part of hippocampal formation. It is tooth shaped and located between the fimbriae of the hippocampus and the parahippocampal gyrus (Snell 2010). It is located underneath the temporal lobe. The hippocampus formation consists of three elements, namely, the *cornu ammonis* (collectively known as the hippocampus), the dentate gyrus, and subiculum (Barrett et al. 2009; Kandel et al. 2000; Nicholls et al. 2001). The hippocampal formation forms the floor of the temporal horn of the lateral ventricle, along with other associated regions (Kandel et al. 2000). The dentate gyrus interlocks with the hippocampus, and forms a C-shaped structure, the subiculum adjoining it (Nicholls et al. 2001).

The dentate gyrus consists of three layers, each of which has an assortment of cell types (Fig. 1). Superficially, there is a relatively cell-free layer known as the *molecular layer*. It contains dendrites of the dentate granule cells. Projections from extrinsic sources such as the entorhinal cortex, through the perforant pathway, are also observed.

The middle layer is known as the *granular or principal cell layer*. It contains the hallmark cells of the dentate gyrus, the dentate granule cells. They are elliptical or rounded cells having spiny apical dendrites. These cells are densely arranged together without glial intervention. Unmyelinated axons known as mossy fibers extend from the granule cells. They project primarily to the CA3 pyramidal neurons. Dentate granule cells are primarily glutamatergic and therefore, excitatory in function. Dentate pyramidal basket cells are present where the granular layer transitions into the polymorphic layer. These cells are large and have a single, aspiny dendrite. They form pericellular plexus that gives its basket appearance. They are the inhibitory GABAergic interneurons.

The innermost layer, known as the *polymorphic layer* or *hilus*, is composed of mossy cells. They are large, stellate or triangular cells, having dendrites that bifurcate further (Amaral et al. 2007).

**Dentate Gyrus, Fig. 1** The dentate gyrus is part of the hippocampal formation that is known to contribute to the formation of new episodic memories along with other important functions. (a) Section of the hippocampal

formation, (b) magnification of the C-shaped dentate gyrus region in the hippocampal formation, and (c) the three layers of dentate gyrus, also depicting the various cells types found in the respective layers

## Neuroanatomy and Neurophysiology

Information from the entorhinal cortex reaches the CA1 region through two excitatory pathways, namely, direct and indirect. The principal output route of the entorhinal cortex is known as perforant pathway. In the indirect pathway, inputs from the entorhinal cortex synapse with dentate granule cells (axons of which are known as mossy fibers). These cells further transmit information to the CA3 pyramidal neurons via the mossy fibers. The axons of CA3 neurons (known as the Schaffer collaterals) extend to the CA1 neurons. From

here, the CA1 neurons project back to entorhinal cortex completing the trisynaptic loop (Bear et al. 2007; Kandel et al. 2000).

Adult neurogenesis is seen in the two regions of active proliferation, namely, the subventricular zone and the dentate gyrus (Purves et al. 2014). New granule cells within the dentate gyrus are produced from neural progenitor cells (Barker et al. 2017). These precursor cells are present in the basal aspect of the granular layer and give rise to neuroblasts. Postmitotically, these neuroblasts move apically and differentiate into inhibitory interneurons. Later on these neurons get

incorporated into the local neural circuits and play a critical role in learning and memory (Purves et al. 2014).

Learning and memory involves long-term changes in synaptic plasticity. Long-term potentiation (LTP) and long-term depression (LTD) has raised a lot of interest among researchers. LTP is an enduring alteration in synaptic strength succeeding a high-frequency afferent activity. In 1973, LTP was first demonstrated by Bliss and Lomo at the perforant synapses with dentate granule cells (Bear et al. 2007; Nicholls et al. 2001). They observed a consequent increase in excitatory synaptic potentials that lasted hours to days, depending on the stimulation parameters. LTP mediated by granule cells is input specific and highly dependent on NMDA receptor activity. Mechanisms that allow the reversal of LTP, for example, LTD are also displayed by the same synapses. LTD is an enduring depression in synaptic transmission. This depression could persist for days and is accompanied by an increase in calcium concentration postsynaptically (Derrick 2007). The dentate gyrus displays competitive modes of learning, specifically the homosynaptic LTP and heterosynaptic LTD (Nicholls et al. 2001). The dentate gyrus plays an important role in the efficient storage of information within the hippocampal formation. This is due to prolonged changes in neurotransmitter release, construction of new synaptic contacts, and the phenomenon of adult neurogenesis (Derrick 2007).

Pattern separation is the ability to separate two closely related images, objects, spatial configuration, etc. It plays an important role in storage and recall of explicit memory. This type of memory comprises semantic (facts) and episodic memory (episodes). It has been demonstrated that there exists a correlation between pattern separation and dentate gyrus. Absence of functional NMDA receptors in the granule cells hamper in performing a pattern separation (Kandel et al. 2000). Kindling is a process wherein an electrical or chemical stimulus is amplified until a seizure occurs. This hyperexcitability induces axonal sprouting, which refers to synaptic reorganization

in the mossy fibers (projections of granule cells in dentate gyrus). The vice versa is also true as studies in animals having focal seizures of hippocampal origin or after kindling show such reorganization (Kandel et al. 2000). One of the major hallmarks of temporal lobe epilepsy includes lack of mossy fiber innervation in the molecular layer (sprouting). Thus, the dentate granule cells play a pivotal role in the pathogenesis of epilepsy.

It has been observed that in an ageing brain, the number of granule cells is preserved. Hence, neuronal degeneration is not responsible for cognitive decline. Axo-dendritic synapses from the entorhinal cortex to the granule cells (perforant pathways) are substantially lost. The weakening of the harmful effects of ageing is intervened by certain factors such as strengthening of pre-existing connections among granule cells. Despite these compensatory alterations, granule cells are relatively more vulnerable than hippocampal cells. MRI studies show that the selective changes in the dentate gyrus can be correlated with memory decline (Chawla and Barnes 2007).

## Comparative Biology

Dentate gyrus is present in the higher-order vertebrates. Extensive research has been conducted on mammals to characterize the dentate gyrus. Generally, brain size and body mass vary proportionately, but some species have a higher brain to body mass ratio, for example, rodents and primates. Studies indicate that the number of granule cells present is dependent on the size of the brain. However, this correlation is not proportionate. Many differences occur even across species of the same class. Morphological and anatomical features, numbers, neural circuits, neurochemical content, etc. of the cells, are some parameters that discriminate them. Several deep convolutions of the dentate gyrus are observed in both human and monkeys. Rodents exhibit uniformity in the morphology of granule cells. In contrast, primates have varying width of granule cells, length of principal apical dendrites, and variable thickness of the molecular layer. Humans have the longest

thorny excrescences of mossy cells, followed by monkeys and rodents (Seress 2007). Cetaceans (whales, dolphins) have a much smaller dentate gyrus with decreased convolutions (Hevner 2016).

Dentate gyrus is a prominent component of the archicortex, which is the oldest brain system. The nonmammalian vertebrates, especially the sauropsids (reptiles and birds), have homologs of the dentate gyrus. These are the medial cortex and medial pallium in reptiles and birds, respectively. The medial cortex is very much like the mammalian cortex. Neurogenesis is observed here thus, it fulfills a role in learning and memory. It has a trilaminar organization and contains the granule neurons with several projections. They project to CA1 and dorsal cortex, unlike the mammalian dentate gyrus. The medial pallium is unilaminar and is characterized by absence of granular cells. Scientists have a divided opinion on the notion that the “avian dentate gyrus” exists where neurogenesis has been observed. It also plays an integral role in spatial learning necessary for flight and migration (Hevner 2016).

## Conclusion

Dentate gyrus is a critical region situated within the hippocampal formation. Adult neurogenesis is crucial for the proper functioning of the brain and it occurs here. It accounts for many fundamental functions such as memory formation and learning, through plasticity. Two types of synaptic plasticity – LTP and LTD are observed in the dentate gyrus. Hyperexcitability in granule cells of dentate gyrus is a core concept in the pathogenesis of epilepsy. It is a part of one of the oldest brain systems and is present in most vertebrates, if not its homolog. Evolution of the dentate gyrus is heavily dependent on the adaptations that the species acquires. It has fascinated the scientific community since time immemorial and still holds great research prospects. Many intricacies of this simple yet complex cortical structure are yet to be discovered.

Edwin Abbott Abbott takes us to a journey into the two-dimensional world in his 1884 novella, “*Flatland: A Romance of Many Dimensions*.” The third dimension, commonly considered as depth, is missed physically as well as perceptually in Flatland; besides that perception of the second dimension for the dwellers of Flatland is at some point between nowhere to bind. In fact, this situation could be generalized as impracticability of perceiving all the dimensions precisely in a physical environment unless you get out of all those dimensions composed the environment and look from a new dimension. For instance, imagine a piece of paper is resembling Abbott’s Flatland. While looking from the third dimension, all dimensions of a geometrical shape (i.e., triangle, rectangle, or circle) drawn on the paper, so the objects and residents belong to Flatland, are evident to us. Thus we can comfortably define the shape drawn on the paper and tell its location along with the direction. Unfortunately, it is not as easy for Square, a resident of Flatland who gets stuck in two dimensions, as it is for us. Square, the narrator of the book, makes the point as follows:

You, who are blessed with shade as well as light, you, who are gifted with two eyes, endowed with a knowledge of perspective, and charmed with the

enjoyment of various colours, you, who can actually see an angle, and contemplate the complete circumference of a circle in the happy region of the Three Dimensions – how shall I make clear to you the extreme difficulty which we in Flatland experience in recognizing one another's configuration? . . . All beings in Flatland, animate or inanimate, no matter what their form, present to our view the same, or nearly the same, appearance, viz, that of a straight Line. How then can one be distinguished from another, where all appear the same? (Abbott 1884, p. 19)

Returning back from such a journey to our homeland, we live in a physical environment (or world) consists of three-dimensions: commonly called width, height, and depth. The spatial locations of all the objects in our environment and their relative positions to each other, and their shapes are defined in terms of a three-dimensional structure. Perceiving our environment in this way allows us to accurately recognize the shapes of objects and surfaces surrounds us, as well as successfully plan and coordinate the various actions we perform in everyday life. If the third dimension, also known as depth, were not available to our perception, tasks as simple as walking on the ground, grasping a coffee cup, coordinating a knife while chopping or a fork while eating spaghetti, driving a car, catching a ball, threading a needle, reaching out for hugging or kissing a loved one, and so on, would be a pain in the neck. Lack of depth perception would even have vital consequences: for instance, without depth perception you cannot discern whether you are about to step on or jump over a dangerous deep hole or simply a manhole cover, exact shapes of surfaces and objects would not be available. Without depth perception, you cannot accurately estimate whether the approaching car will crash you before you safely cross a road, in fact, you cannot even cross a road, direction of navigations would not be available. Without depth perception, a frog cannot catch flies with its tongue while starving, planning and coordinating actions would not be available.

Unlike occupants of Flatland, animals of our homeland, are equipped with perceptual systems such as tasting, smelling, haptic, auditory, and visual systems (Gibson 1979), and they live

in harmony with their environment. Such symphony saves animals from travelling to the fourth dimension to perceive their physical environment as it is in three-dimensional structure.

There are three different perceptual systems that are directly related to depth perception. The first one is the haptic system that requires information to be gathered directly from the environment by touching. Touching along with reaching is especially critical for infants while learning three dimensional structures of objects and developing depth perception. It is not surprising that infants are used to love touching every single object and all surfaces with full of curiosity but this habit fades away as they are growing up. Infants' miserable sight might be one reason of that. They cannot visually focus on objects that stand out of 8–10 inches (20–25 cm) distance from their face. Their eyes are not well coordinated, and they do not have the control of their eye-movements, neither eye-body coordination skills do they have. It takes 2 years for infants to develop a normal vision and 7 years for a fully skilled vision. On the other hand, infants start touching while in the womb, and they are born with highly sensitive skin; around 3 months of age they also start reaching. In such sense, touching is in favor for depth perception and understanding three-dimensional structure of the objects and surfaces around during childhood. Unfortunately, one handicap of haptic perception is that touching is only available within arm-length distance. Because of this boundary, haptic perception is not really practical on evaluating the long distance or the three-dimensional shape of giant objects. Touching takes a step back in the adult's process of depth perception although it still contributes in some way. There is indeed some exceptional cases where touching is still a blue eyed boy for adult, just like for children; for example, in the case of blind people. Eşref Armağan, who is a congenitally blind painter lives in Turkey may set the best example of it. He challenged scientists' knowledge about depth perception they had had until run into Eşref Armağan and saw his art. He uses pictorial information in his paintings to reflect depth that thought to be available only through vision by

then, but haptic. Eşref Armağan has never had vision to understand such information; he is used to see all details by through his fingers.

The illusions for sighted people due to depth information in Eşref's drawings are striking. Inaccuracy in touch may be less to do with depth information than vision, and more to do with grouping areas in 2D [two-dimensional]. Heller (2003) reports many tactile illusions for the blind, but no effects that can with certainty be ascribed to pictorial depth information. In contrast, studying grouping, Heller et al. (2003) found flat forms embedded in larger forms hard to discern in touch; they were grouped with the embedding form. (Kennedy and Juricevic 2019, p. 11)

Auditory is the second perceptual system that contributes to depth perception at a considerable degree. Unlike haptic, auditory is not much convenient on discovering the three-dimensional shapes of objects and surfaces; that is not because it is impossible but it requires to develop an exclusive skill to do so like bats and dolphins do. Yet, auditory has an edge on haptic in detecting spatial location of objects that are farther away from arm-length distance. Auditory could certainly be a reliable guide to determine the relative direction of the objects along with the distance from the perceiver. Otherwise a bell on the collar would not be able to help you to find your little playful kitty while it is hiding from you. Objects which somehow get our attention in the environment do not always fall within our visual field or arm-length distance. When that is the situation, auditory system takes all responsibility in evaluating the relative position of the object. For example, imagine you are camping in a jungle, and while resting in your tent at midnight, you hear kind of a strange sound that could be made by a hostile person or a wild animal. You have nothing to defend yourself and you are about 3 miles (5 km) away from your car. You, now, have two options ahead of you: either you decide to stay in your tent quietly which is the shrewd reaction to do if the beast is just right there around the tent. If you decide the beast is not really close, you may choose to sneak off to your car. Then, you have to make sure that the beast is not in the same direction you run towards. Otherwise, you end up falling

into the lap of the beast. The sound you hear is the all source of information on your hand to make such a life matter decision; if you listen to it carefully, your auditory system will reveal every detail you need like how far the beast is from you, in which direction it is moving, and how fast.

What haptic and auditory systems mean to depth perception have been discussed, so far. Each one has different advantages favorable for different aspects of depth perception. They are counterparts each of which completes deficient part of the other for a completed depth perception. In general, neither one is better than the other. However, the third one, visual system, is capable enough to be able compensate in the absence of both haptic and auditory systems by its own for the depth perception in all respect. Visual system is the one we most rely on among all perceptual systems we have and the one we are most afraid of losing.

RECENTLY, I ASKED a group of friends which sense they would miss the least if they had to lose one. Most people chose smell. No one chose vision.

If you lose vision, you lose your most important sense for knowing where things are. Vision allows us to perceive the shape of objects and their arrangement in the world around us, an ability that impacts nearly everything we do . . . Among all our sensory systems, vision's contribution is uniquely important for the brain's assembly of a sense of space. (Groh 2014, p. 7)

Visual system is important to us as playing a major role in our understanding and identifying the environment, and interacting with it. Considering the vision's essential functioning in perception, it is understandable that vision is not a simple process. The studies that dedicated to understand visual perception dates back in time until the era of philosophers lived in ancient Greece. Not alone has it been interest of neuroscientists and psychologists, but philosophers, mathematicians, artists, and astronomers, too. Democritus, Plato, Euclid, Alhazen, Leonardo da Vinci, Rene Descartes, Johannes Kepler are only a few famous historical figures who paid attention to explain vision. People from all over the world (i.e., India, China, Arabia, Anatolia, and Europe) in different disciplines have

cumulatively formed today's understanding of vision (Groh 2014; Howard 2012).

During the early stage, even the source of the information that enabled the vision and its direction between eye and perceived object or a target point was a mystery. It was mid-eleventh century in the Common Era when the first time Alhazen pointed out that the light reflecting from object to eye contains all the information needed for the vision. Albeit he revealed the obligation of one-to-one relation between the eye and the perceived object or target point, he claimed that the perception should be formed in the lens; otherwise we would perceive the world in upright position. It took until seventeenth century when Kepler's work revealed the optical basis of visual perception that is the discovery of the retinal image (Gilchrist 2014; Groh 2014; Howard 2012).

Today, common knowledge has it that vision starts when ambient light hits the retina of the eye. The retina captures only two-dimensional images of the three-dimensional world. Yet, we clearly perceive the world as being three-dimensional. What allows the visual system to reconstruct its view of the three-dimensional world from those two-dimensional retinal images? Though not a comprehensive explanation is revealed yet, there are some justifications that could be counted as the answer. Before continue with those notes, the heart of the problem with two-dimensional retinal image needs to be clarified further.

It is quite problematic to perceive the three-dimensional world through two-dimensional retinal images because the two-dimensional retinal images could be inherently ambiguous. The ambiguity basically arises from the missing third dimension (depth); different objects in different sizes, positions, or distances sometimes could be projected onto very similar retinal images; in other words, although they have differences in the real world, they may be conflated in the retinal images. Such ambiguity is called the *inverse projection problem* (Palmer 1999; Pizlo 2001).

The inverse projection problem causes failures in depth perception at the level of the retinal

images. Luckily, our visual systems are capable of preventing or at least decreasing such failures by resolving the ambiguity of the inverse problem on the retinal images. Our visual system relies on different types of depth cues to make up for the losses of depth due to the inverse projection problem. In the following part, those cues are briefly noted along with their meanings in the order they generally classified. Depth cues are mainly divided into two broad categories: oculomotor and visual.

### Oculomotor Cues

The term "oculomotor cues" refers to the information the brain receives from eye muscles while fixating the eyes on a target point, usually that is specifically an object. Such information is practically usable only for arm's length distance. For example, if you fixate your eyes on an object you are holding at eye height within arm's length, your visual system will benefit from the oculomotor information cue to decide where the position of the object is, depth-wise. If you slowly move the object towards and away from you, you can feel it through oculomotor feedback. There are two types of oculomotor information cues:

#### Accommodation

The ciliary muscles, which are located in the ciliary body around the iris of the eye and innervated by oculomotor nerves, accommodate the lens in order to focus on an object at different distances within about an arm's length radius. When an object is nearby, the ciliary muscles contract and hence make the lens rounder. In contrast, when the object is more distant, the ciliary muscles relax and hence make the lens flatter. By doing so, the ciliary muscles, on one hand, allow us to focus on objects for clear vision; on the other hand, they provide useful feedback to our brain for the depth interpretation about the object.

#### Vergence

Movements of the two eyes in opposite directions (when both of them move either inwards or outwards; towards or away from each other) are called vergence eye movements:

To be able to fixate our eyes on an object moving toward our face, we move the eyes inward; this is called convergence. On the contrary, eyes diverge as an object gets farther away from our face; this is called divergence. Vergence eye movements help to maintain a single image in binocular vision of an object moving in the depth dimension. Moreover, the feedback from the muscles that control vergence eye movements provides depth information about the object (Mon-Williams and Tresilian 1999; Mon-Williams et al. 2000). Accommodation by the ciliary muscles (as described above) is connected to vergence eye movements – both usually happen together when an object is moving in depth. Yet, vergence provides more accurate estimations of depth perception as compared to accommodation.

### Visual Cues

While oculomotor cues are considered to be internal cues, visual cues have a more external source: usually physical, psychological, and pictorial information cues. Visual cues can be categorized into two groups as binocular and monocular.

#### Binocular Cues

Binocular cues are taken to be the most essential cues for depth perception. Because these cues are the most powerful among other cues, our visual system primarily relies on this information as planning and performing actions (for a review, see Goodale 2011).

When we fixate both eyes on one object (or at a single point), two eyes see the same object from slightly different perspectives because of the space between them, known as the interpupillary distance (IPD), which averages about 2.5 inches (6.3 cm) for an adult human. As a result, we have two retinal images, which differ slightly from one another. Although we have two different retinal images, we experience only one visual image (under normal conditions); the brain forms a single, three-dimensional visual image from two different two-dimensional retinal images. The differences found between the two retinal images serves as a source of information for depth perception (Bishop 1970; Julesz 1971). For a better understanding of this source of

information, it is necessary to first understand the geometry of the “*horopter*.”

When we fixate both eyes at a single point, the fixation point, together with centers of the lenses of both eyes, all lie on an imaginary circle. On this imaginary circle, we can picture two arcs with the centers of the lenses of two eyes being endpoints; the one that contains the fixation point midway along its length is called the horopter. All images along the horopter are projected onto corresponding retinal points in the two eyes, thus the horopter is also known as the set of points with zero disparity (Von Noorden 1996). All the points in the visual field that are off the horopter fall on analogous (noncorresponding) retinal points in the two eyes. Moreover, as the distance from the horopter increases, image difference between noncorresponding points in the two retinæ also increases. This difference between the two retinal images is called retinal disparity. There are two types of diplopia, or double-vision: crossed disparity and uncrossed disparity. Crossed disparity is created by the images located between the horopter and the observer; these images are usually projected on the temporal hemiretina points (the outsides of the retinæ). On the other hand, uncrossed disparity is created by the images that are located behind the horopter; these images are usually projected on the temporal hemiretina points (Von Noorden 1996).

The retinal disparity causes diplopia. Yet, we usually do not experience the diplopia so it is called physiological diplopia – it happens on the retinæ, but not in our minds. The reason we do not experience this diplopia is that our brains fuse the retinal disparity within Panum’s Fusional Area. It is a specific area around the horopter that allows fusion. This area is narrowest at the fixation point and getting wider towards the periphery. The process of fusion is called stereopsis (Von Noorden 1996).

#### Monocular Information Cues

Although binocular vision is very powerful for depth perception, we can perceive depth even in the absence of binocular vision by relying on monocular information cues.

**Dynamical Cues** Motion provides depth information that is available even to monocular vision. Goodale (2011) described studies which revealed that one-eyed people seemed to use retinal motions resulting from head movements during reaching actions. This suggests that dynamical cues are the second most reliable depth information cues after binocular cues. Consistent with Goodale, Boring (1942) found motion parallax, which is a kind of dynamical cue, to be the most important cue after binocular cues. On the other hand, Nakayama and Loomis (1974) considered both to be primary information cues for depth perception in their comparison of binocular cues and optical velocity information, which is a specific kind of dynamical cue. They claimed that binocular cues might be more useful for actions, such as reaching, that take place in the near environment whereas optical velocity information might be more useful for more distantly directed actions such as throwing or observing.

*Motion Parallax* Motion parallax is the term used to describe optical displacement of an object in the visual field while the observer is in motion. Helmholtz's (1925) definition of motion parallax is two-fold: first, he asserted that motion parallax information allows us to judge absolute distance of the object from our own position. While an observer moves in one-direction, points, relatively fixed in the observer's visual field, provide a sense as if they are moving in the opposite direction and their apparent angular velocity to the observer is inversely proportional to their real distance. Thus, their real distance to the observer can be inferred from their angular velocity. Subsequently, Gibson and his colleagues (Gibson et al. 1955) showed that this is true only if the speed and direction of the observer are known. The second part of Helmholtz's definition claims that motion parallax information allows us to discriminate objects sitting in different positions in depth. Helmholtz (1925) used a foliage and branches example: it is almost impossible to distinguish a tangle of foliage and branches if viewed in stillness. Yet immediately upon the presence of motion, we can appreciate the separation of each

leaf and branch and become aware of their relations to each other in space. Gibson (Gibson et al. 1959) suggested these two approaches were independent and needed to be studied separately.

Later on Nakayama and Loomis (1974) explained how to extract depth information from optic flow based on a formula that describes the pattern in the optic flow. Optic flow is a related but broader notion than motion parallax. Nakayama and Loomis emphasized the distinction between motion parallax and optical flow information: motion parallax refers to only a small number of focal objects; optical flow information, however, is the totality of optical motions (Gibson 1950). The relative motion between an observer and the environment produces optic flow information. Because optical flow refers to all points in the visual field rather than a single focal point, it is represented by what is called a velocity field. Each vector, in the velocity field, is associated with optical motion of a point and the magnitude of the vectors is inversely correlated with the distance of the point. In other words, closer points move with greater velocity. Variation in distance generates motion parallax gradients. Hence, motion parallax provides information about the relative depth of the points.

Another inference that can be made from optical flow structure occurs when two adjacent points in the image have significantly different velocity magnitudes; if those adjacent image points are associated with two distinct points in depth, then the difference between their velocity magnitudes will be greater. Such information is a useful cue regarding the separation of distinct surfaces. Yet this information usually accompanies cues such as accretion and deletion that will be explained shortly after expansion and contraction.

*Expansion and Contraction* Imagine you are moving towards an object with an angular position of 0—straight ahead. The angular velocity of the object will be 0, and so the magnitude of angular velocity will be useless for depth perception. In such a case, expansion and contraction information helps to provide depth perception. While an observer moves closer to an object, the object will appear as if it is expanding because

of the change in the retinal image size of the object. Contrarily, while moving further away from the object, the object will appear as if it is contracting within the retinal image. The degree of expansion or contraction will be inversely proportional to the distance between the object and the eye. For example, assume you are in the middle of your room and looking at a tree outside the window. You are able to see only part of the tree. With each step you take towards the window, a bigger part of the tree will be available to your sight. Eventually, you will be able to see the whole tree when you reach the window. This experience could be explained as follows: while you are moving towards the window, the expansion degree of the window is greater than the expansion degree of the tree because the window is closer to you. You can use such information to infer the depth *order* between two objects. If you know your speed, you can also infer the absolute distance of the objects.

*Accretion and Deletion* When two opaque objects are located at different distances in depth, the nearer object partially or wholly covers over or reveals the more distant object as the observer moves. (Gibson 1979). Imagine that you are sitting in a theatre, in the seventh row of seats, and trying to see the picture on the scene. Unfortunately, the head of the person sitting in front of you in the sixth row blocks the scene. If you try to lean forward, the person's head will cover a greater part of the picture. Is his/her head getting bigger as you are leaning forward? Of course not. Actually what is happening here is exactly the same as with the window-tree example: as you are leaning forward both the picture and the person's head are expanding however because he/she is closer to you, the degree of expansion of his/her head is greater than the degree of expanding of the picture. Therefore, you are experiencing deletion in the picture on the scene. If you lean backward rather than forward, you experience accretion of the picture on the scene. Moreover, if he/she sits further from you and closer to the scene, the difference between the expansion/contraction degrees of the head and the picture will be smaller;

so, the accretion/deletion will occur more slowly. Hence, the rate of accretion or deletion is able to provide relative depth information about objects. Accretion or deletion will occur not only during backward/forward movements of the observer but also during sideways movements. However, with accretion and deletion information revealed by sideways movements, you can still easily infer depth order.

**Static Cues** While you are looking through a peephole to see what there is on the other side of the door or wall, binocular vision is not available at all and motion is very restricted as you are not allowed to move backward-forward or side to side. Nonetheless, thanks to static cues, so you can still experience the depth in your view.

Static cues are also called pictorial cues and often used by visual artists in two-dimensional paintings and photography to reflect the depth sense. From time to time, you may run into such paintings or photographs that make you strongly feel as if you are a part of the environment via the sensation of depth depicted in the picture. If you think you have never come across one of those, just take a break from reading this entry and check these paintings: *The Dance Class* by Edgar Degas (1874), *A Sunday Afternoon on the Island of La Grande Jatte* by Georges Seurat (1884), *Cafe Terrace at Night* by Vincent Van Gogh (1888), *Paris Street; Rainy Day* by Gustave Caillebotte (1894), and *The School of Athens* by Italian Renaissance artist Raphael (1511).

*Occlusion* Considering Edgar Degas's painting, "The Dance Class," which ballerina is closest to you in the painting? Although it is a two-dimensional picture with no dynamical cues, you can easily say that the ballerina who wears a big red ribbon barrette on her hair on the left hand side is closest with no doubt. Your confidence relies on a basic depth cue called "occlusion": some part of the girl, which seems closer, is partially occluding the other girls. Occlusion indicates the relative distance but not absolute distance. It is hard to tell the absolute distance between people in the picture based only on their occlusion cues.

*Relative Size* If one of two similar or identical objects in an image looks bigger than the other one, it will give the impression that the one that looks bigger is closer. Reconsidering your answer above to the question regarding the closest ballerina in the painting, “The Dance Class,” the occlusion is not enough by itself to say that the ballerina who wears a big red ribbon barrette on her hair on the left hand side is closest with no doubt. She is not occluding the dancers on the right hand side but she is the biggest in terms of size although they should be around same size. Thus, your confidence relies on both depth cues called “occlusion” and “relative size.”

Note that the logic of relative-size information applies to expansion and contraction in motion, and, together with occlusion, it is also related to accretion and deletion.

*Familiar Size* Our knowledge about objects can help in depth perception too. For example, if we see a toothpick, a baby, and the Eiffel Tower, all appears to be the same size, in a picture, we will think that the toothpick is closest and the Eiffel Tower is the furthest object. Moreover, we can infer that the distance between the toothpick and the baby is smaller than the distance between the baby and the Eiffel Tower.

*Distance from Horizon Line* Objects and surfaces appear closer to the horizon as their distance becomes greater. Picture a moment at a beach, you are watching people swimming in the sea; you do not hesitate to assume that the person looks closest the horizon is the furthest away from the beach.

*Shadows, Shading, and Lightning* Shading and lighting patterns on an object or surface provide powerful cues as to the three-dimensional structure of the object or surface. You can make a circle appear as convex or concave simply changing the lightning and shading. The characteristics of cast shadows help us to determine the position of objects and the shapes of the environment. For example, a cast shadow of a flying bird cannot be connected to the bird. The cast shadow of a telephone pole does not look same on a

stone as it is on a street; the stone has a convex surface whereas the street is flat.

*Atmospheric Perspective* Because of the atmospheric effect, objects that are further away appear bluer and less distinct than nearer objects.

*Linear Perspective* Parallel lines appear to converge towards a vanishing point on the horizon or close to the horizon. A railroad, viewed from one standing upon the tracks looking along them, might be the best example to clarify linear perspective. You can also visit and see some paintings in the gallery of Esref Armagan who is the congenital blind painter mentioned above.

*Texture Gradient* Considering a walkway and a wall, two different surfaces both are consisting of similar cobblestones. Indeed both surfaces have a homogenous spatial texture. But, in the real world, we see a heterogeneous spatial structure on the walkway. Based on the rate of change in the density of the pattern, we can easily distinguish a walkway from a wall, which has a homogeneous pattern. The increasing density of the pattern indicates an increasing angle from the eye and that increasing angle yields increasing depth information.

If we express this in a more general way: the volume of gradient specifies the slant of a surface in the world with respect to the line of sight. Furthermore, simple changes in gradient can define corners and/or edges. If the change of gradient of density is smooth, it yields a corner; if there is a jump in the gradient of density, it yields an edge or, in other words, two separate surfaces (Reed 1988).

## The Gibsonian Approach to Depth Perception

Earlier theories attempted to explain visual perception as a sensation-based phenomenon that found the retinal image to be central to visual perception. Those theories struggled, however, to explain three-dimensional vision based in two-dimensional retinal images. Some early

theorists (e.g., George Berkeley) suggested that depth perception could not be explained based purely on the senses *per se*; sensation was impoverished to explain perception without relying on resource to knowledge about the world such as provided by experience. These theorists explained depth perception as occurring by first having the sensation and then inferentially constructing the space.

Gibson rejected this sensation-based approach to visual perception. Instead he introduced the information-based approach. According to the information-based approach, visual perception cannot be explained based on retinal images; perception is detecting information, which exists as invariant variables in the optical array. Optical array is the pattern of structured light reaches the eye with respect to point of observation and contains all the information for visual perception directly without need for any mental representation or memory. Retinal images are just a sampling from the optical array. Hence, information is not a static two-dimensional image on the back of the eye. Instead, it is available to be detected in the optical array and specific to surfaces and lay-outs. Depth is not really lost (Braund 2008).

Although Gibson eventually rejected the sensation-based approach, he had had missteps and confusions before developing his final theory. In his early studies, Gibson tested slant perception based on different texture gradients (Reed 1988). In the experiment, subjects sat in front of an aperture in a wall. Through the aperture, they were able to see the texture of an upright screen behind the wall though the edges of the screen were occluded from their sight by the wall with the aperture. The upright screen was painted different texture gradients. These gradients allowed Gibson to manipulate the patterns of retinal images in his participants. The task of the subjects was to decide the optical slant they observed on the screen. The hypothesis behind the experiment was that the gradient of texture density with no other clues available would yield an impression of a receding surface. Results revealed that subjects thought they were seeing slanting surfaces despite the fact that the surface in the back was

always upright. Moreover, greater changes in the texture density resulted in greater perceived slants. However, there was a problem: the slant was always underestimated, even though texture gradients co-varied with perceived slant.

Subsequently Gibson decided to focus on perceptual psychophysics rather than sensual psychophysics. In his optical tunnel experiment, he was studying the optical conditions that give rise to surface and space perception. This was neither a physical tunnel nor a special retinal image; you will read more about what an optical tunnel is, in a moment. Gibson was no longer attempting to control the formation of retinal images but instead was controlling the stimulation available to observers' visual systems that enabled them to obtain retinal images.

In the optical tunnel experiment, Gibson attempted to manipulate and studied optical transitions. The tunnel apparatus controlled the gradient of optical transitions in the available stimulation by different arrangements of the transitions and different observation positions. The optical tunnel was in two arrangements. Plastic sheets are arranged with alternating smooth black and white coloring, with central holes cut out carefully so that each sheet acts as an aperture for the sheets behind it. First, the tunnel creates a constant density of optical contrast, a heterogeneous, inverse gradient in the world. This looks flat, canceling gradient in the optics, homogeneous. Second, the tunnel creates an increasing density of constant, no gradient in the world, homogeneous. This displays a visual tunnel, yields gradient in the optics, heterogeneous.

In the tunnel experiment, Gibson provides the information of a surface even though there is no real surface there. The optical structure tells the same thing as optic flow structure. The gradient in the optic flow is identical. He distinguished the world and the optical structure and studied the relation between them. The optical structure is different than the world structure but they are uniquely related. Depth is not lost; there is enough information in the structure of light.

The significant change in Gibson's methodology was that he was no longer trying to make retinal images replicate surfaces; instead, he was

trying to control the stimulation available to the eyes of his observers.

## Conclusion

Depth perception is perceiving the environment as in three-dimensional coordinate systems. It is all about knowing where things are, what they are, and what we can do with them. In this manner, depth perception provides two critical aspects of understanding our environment: clarifying the shapes and evaluating the spatial locations of the objects. Neither haptic nor auditory system alone is capable of encompassing the two aspects of depth perception. The nature of haptic confines its employability within arm-length distance. Yet, haptic system is proficient on evaluating the shapes of the surfaces and objects, so it can precisely tell us what they are and what they afford. Haptic is primarily used by infants and blind people. Auditory system is a counterpart of the haptic system; they are integral part of each other for the sake of depth perception with no strings. In other words, haptic system is strong where the auditory system is weak and vice versa. For example, haptic system works well within arm-length distance, and auditory system steps in while the distance getting greater than arm-length. Haptic clearly state what the object is whereas auditory confidently decides where the object is with respect to our position. Visual system is not affected in the absence of either one or both of haptic and auditory systems; vision still capable of promising a fully completed depth perception.

## Definition

A temporary period of reversible, suspended development that can occur in some invertebrates, and in mammalian and nonmammalian embryos. It is commonly induced as either a response to unfavorable environmental conditions or as a mechanism to separate the timing of mating and the length of pregnancy.

## Introduction

Developmental arrest is a widespread phenomenon occurring in a diverse range of species at a multitude of different life stages and in response to a large variation of stimuli. Much of the diversity is species-dependent. However, all forms confer some sort of selective advantage that enables the species to maximize its reproductive success. In general, there are two main forms of developmental arrest: diapause and quiescence (or torpor). Diapause is a gradually induced arrest and involves a downregulation or arrest of cell division and suppression of metabolism. It may be hormonally regulated and generally occurs prior to the onset of predictable, unfavorable conditions (e.g., in response to seasonal changes). In contrast, quiescence occurs in response to an unexpected change in environmental conditions which are not conducive to growth and/or survival. Some species are also able to delay hatching in response to environmental conditions, but this does not normally involve a reduction in metabolism or a delay in development.

In mammals, diapause occurs during pregnancy and has been classified into two types, embryonic diapause and postimplantation diapause. During embryonic diapause, the arrest occurs prior to the embryo attaching to the uterus (implantation), while postimplantation diapause or delay occurs after the embryo has attached to the uterus. Both types of arrest can be induced by either facultative mechanisms (lactational or nutritional availability) or seasonal mechanisms (photoperiod, temperature, or rainfall).

Members of three orders of nonmammalian vertebrates are able to undergo forms of developmental arrest, namely, fish, reptiles, and birds. These species undergo diapause in response to environmental factors and in the oviparous (egg-laying) reptiles, diapause can occur either prior to or postoviposition. In addition, the embryos of most species of reptile, and some fish, can employ torpor (quiescence), at any stage during egg incubation, while the majority of oviparous species can undergo delayed-hatching. Diapause also occurs in several viviparous (live-bearing) species of reptiles and fish.

In invertebrates, developmental arrest can take two forms, diapause and quiescence, and can occur at many different stages of the life cycle. Diapause may be hormonally regulated and/or occur in response to signaling cues that are predictive of forthcoming environmental change (e.g., photoperiod). Quiescence is a common reproductive strategy which allows invertebrates to respond to adverse environmental changes (e.g., anoxia or desiccation), which, depending on the species, they can survive for periods of weeks to years.

## Embryonic Diapause in Mammals

Embryonic diapause has been identified in over 130 species of mammals in eight different orders. It occurs early in pregnancy, when the embryo consists only of a ball of cells (between 30 and 500 cells, depending on the species) and is free-floating in the uterus prior to implantation. During diapause, the cell cycle of the embryo is either arrested or greatly retarded, while maintenance of a basal metabolism and low levels of RNA and protein synthesis ensure the embryo remains viable. Depending on the species, embryonic diapause can be either lactationally or seasonally induced and can last for anywhere between a few days to 11 months. In general, seasonal diapause is the predominant form of diapause in mammals with only the rodents and the macropods (kangaroos and wallabies) undergoing lactation-induced diapause. The tammar wallaby (*Macropus eugenii*) is unusual in that diapause can be both lactationally and seasonally induced, dependent on the time of year. Along with the tammar, the best understood diapause mammals are the mouse, *Mus musculus* (lactationally induced diapause) and the mink, *Neovison vison* (seasonally induced diapause) (Fenelon et al. 2014).

In the mouse, mating occurs within 24 h after giving birth, and it is the metabolic stress of suckling the young that causes the embryos to enter into a lactationally induced embryonic diapause for a period of 2–7 days on average but can be up to 14 days. This is dependent on the number of

suckling young and is postulated to delay birth since lactation in the mouse last for only 19 days while pregnancy is 20 days long. Diapause can also be experimentally induced in the mouse by ovariectomy and daily progesterone injections with reactivation occurring after injection of estradiol (Fenelon et al. 2014).

In the mink, embryonic diapause is obligate, occurring in every pregnancy and is dependent on photoperiod and controlled by the relative levels of melatonin and prolactin. In the Northern Hemisphere, mink mate in early March and the embryos are in diapause during periods of short photoperiod. Embryos then remain in diapause until after the spring equinox (21st of March in the Northern Hemisphere) when day length begins to increase and the embryos reactivate. This allows pregnancy in the mink to be extended by a number of weeks ensuring the separation of mating and parturition so that young are born when conditions are more favorable to survival (Fenelon et al. 2014).

### Postimplantation Diapause in Mammals

To date, postimplantation arrest has only been reported in the order Chiroptera (bats). The arrest normally occurs at a specific stage of development, either just after implantation, at gastrulation, or at primitive streak formation. Depending on the species, the period of delay can be either similar for all females or highly variable in others and can last for anywhere between 10 days and 8 months. Many species of bats have two pregnancies each year and only one of these tends to be arrested. For the majority of bats, the period of arrest often coincides with winter hibernation and may be due to either a decline in food availability or temperature. However, the precise stimuli and physiological regulation remain unknown. Schreiber's bent-winged bat (*Miniopterus schreibersii*) is unique in that it exhibits both embryonic diapause and a period of postimplantation diapause when the bats are in hibernation (Krishna and Bhatnagar 2011).

### Developmental Arrest in Nonmammalian Vertebrates

In the nonmammalian vertebrates, developmental arrest can occur at multiple time points in development, depending on the species. In addition, the environmental stimuli that arrest and restart embryonic development are species-specific and vary widely.

In fish, there are currently two confirmed species of Chondrichthyes (cartilaginous fish) in the subclass Elasmobranchii that undergo diapause, the bluntnose stingray, *Hypanus say*, and the Australian sharpnose shark, *Rhizoprionodon taylori*. In these species, ovulation and fertilization take place immediately after mating and development is arrested at the blastodisc stage for a period of 7–10 months. The control mechanisms are currently unknown (Waltrick et al. 2012). Developmental arrest also occurs in the Osteichthyes (bony fish) and is particularly predominant in the killifish, (order Cyprinodontiformes), which occupy temporary aquatic habitats. For example, in the turquoise killifish (*Nothobranchius furzeri*), seasonal drying of their habitats kills the adults and juveniles but the eggs can enter into diapause and remain arrested until the return of the rainy season, thus ensuring survival of the species (Hu and Brunet 2018). Delayed hatching is also a very common phenomenon in killifish embryos while quiescence normally occurs in response to anoxia (Martin and Podrabsky 2017).

In reptiles, developmental arrest is common in oviparous species and can occur at three different stages in the life cycle, either early preoviposition, late gastrulation (most common), or in the pre-hatching embryo, with some species able to undergo all three forms. Although diverse, the main environmental influences that affect whether arrest occurs are oxygen tension, temperature, or rainfall. In several viviparous species, delayed parturition can also occur, but this is at the end of embryonic development.

In oviparous reptiles, diapause can be either preovipositional or postovipositional. Preovipositional diapause ensures that all eggs are laid at the same developmental stage. It normally

occurs during early embryogenesis but can occur during gastrulation in some species. Resumption of normal development then occurs after the eggs are laid (Andrews 2004). Postovipositional diapause occurs, while the embryos are gastrulae and can be obligate in some species or dependent on environmental factors in others (Andrews 2004). There are also two additional forms of post-ovipositional arrest, delayed hatching, and torpor. Delayed hatching keeps the embryo within the egg in response to adverse environmental conditions and permits synchronization of hatching to optimal environmental conditions. In Australia, many frog species lay their eggs on land in areas that later flood, and hatching may be delayed for weeks if the eggs are not submerged. Alternatively, torpor is used by embryos, at any stage prior to hatching, to survive brief periods when temperatures are too low to support development (Rafferty and Reina 2012).

Many avian species are also able to undergo developmental arrest but this is only post-ovipositional and is primarily through the use of torpor after oviposition to prevent development of embryos until all eggs in the clutch have been laid to allow synchronization of the development and hatching of the clutch.

## Developmental Arrest in Invertebrates

Developmental arrest is widespread among the invertebrates with representatives in all families except Echinodermata (starfish and sea urchins). The most common form of developmental arrest in invertebrates is diapause, which can occur at various stages of the life cycle, depending on the species. There is considerable diversity in the various environmental conditions under which diapause can be induced in invertebrates, with the most common cues being photoperiod, temperature, and overcrowding. Two of the most well-studied examples of diapause in the invertebrates are the nematode, *Caenorhabditis elegans* and the brine shrimp, *Artemia franciscana* (Hand et al. 2016).

Many nematode species are able to undergo diapause, but while many parasitic species

undergo diapause as an obligate part of their life cycle, many free-living species are able to undergo diapause only in response to environmental triggers. During development of the larval stages in the free-living nematode *C. elegans*, exposure to unfavorable growth conditions arrests development and the larvae enter into a reversible diapause stage known as dauer. Dauer larvae are characterized by numerous morphological changes which result in an extended life span and confer an increased resistance to stress. Once conditions improve, the dauer larvae recover and continue normal development (Padilla and Ladage 2012).

In the brine shrimp, females can shift from giving birth to live young (eggs hatched internally) to oviparous reproduction (eggs develop and hatch outside maternal body), depending on the time of the year. In oviparous reproduction, the eggs are released when the embryos are at the late gastrula stage. The eggs then remain arrested with a greatly suppressed metabolism until environmental conditions improve. The cue to shift from live births is a change in photoperiod, signaling the onset of winter, and ensuring the survival of the young as diapause eggs (Hand et al. 2016).

## Conclusion

In summary, the biological mechanisms of developmental arrest are diverse and wide-ranging depending on both the species and their habitat. There have been a number of theories postulated for the evolution of development arrest. In part, this depends on the mechanism via which the arrest is induced, and in insects at least, diapause is thought to have evolved independently multiple times given the wide variation and occurrence of diapause at different life stages even in the same genus (e.g., egg, larval, and adult diapause forms exist in the mosquito genus *Anopheles*). However, a number of generalizations can be made on the selective advantage developmental arrest concurs in all species. First, developmental arrest synchronizes the production of young with environmental conditions conducive to survival and growth. In many species of mammals, diapause enables the

separation of mating and birth to suit the conditions. Second, it often serves to help individuals survive environmental conditions that are lethal to developing embryos. In the invertebrates, this can also be a mechanism to reestablish future populations; either when conditions are too harsh for the adults and juveniles to survive or via the transport and dissemination of the species to new locations. Finally, quiescence (or torpor) allows embryos to respond to, and survive, adverse environmental conditions.

## Diallel Design

Surajit Bhattacharjee and Avik Sarkar  
Department of Molecular Biology and  
Bioinformatics, Tripura University,  
Suryamaninagar, Tripura, India

## Synonyms

[Combining ability](#); [Twin study method](#)

## Definition

The term diallel implies all probable crosses among a collection of set of animals. According to Hayman, a diallel cross can be defined as the set of all possible crosses between several genotypes, which may be individuals, clones, homozygous lines, etc. (Hayman 1954a, b). Diallel cross is the most balanced and systematic approach to analyze continuous variations among the genotypes of individual taken for

study. Since almost all the genetic information are available in the parental population so the propensity to carry out diversified breeding techniques can be done within a very short span of time.

## Background Description

The diallel mating design has been successfully applied in the plant breeding studies over more than 50 years. Not only in plant mating analysis but in many cases this technique is extended to analyze genetic mating combination in animals study. Since, 1950 this study was further aggravated to estimate genetic variance in different components like plant breeding and animal genetics. Though the analysis suffered a major drawback and criticism on validating the usefulness of its applicability, researchers use diallel design to evaluate the indispensability of the mating pattern taken for consideration (Griffing 1956).

The diallel mating design generally estimates the variation of quantitative characters in the genetic components like assessment of plant seed quality. The estimation is also performed to deduce the combining ability of the different inbred lines which participate in the different crosses taken into consideration.

## Types of Diallel Mating Design

The diallel mating design methods can be classified as follows (Griffing 1956).

1. **Partial Diallel Design** – This is a type of diallel design where a portion of required cross is made. This means in this study design each parent is not mated with every parent in the group leading incomplete or partial genetic cross.
2. **Systematic or Progressive Mating Scheme** – In this design the crosses which are made, they generally fall in particular diagonals. The diagonals are chosen in such a way that no one parent is interfered in more than few crosses.
3. **Disconnected Diallel Scheme** – This pattern of design is characterized by the parents who are categorized into tiny groups and diallel or

half diallel matings are done within each individual group.

## Methodologies for Studying DD

Griffing (1956) and his coworkers have analyzed the DD elaborately using different models. The mating ability of a particular species is initially portrayed in a tabular form then combining abilities are identified accordingly.

Two types of combining abilities are present:

### 1. General Combining Ability (GCA)

The ability of the inbred line is the mean performance of the hybrids that this line reproduces with other lines chosen from a random mating population. It is estimated from half-sib families.

### 2. Specific Combining Ability (SCA)

This refers to a pair of inbred lines which are involved in a cross. In this cases certain combinations might do relatively better or inferior than would be predicted on the basis of GCA effects on two lines involved in the study. It is generally deviation of a particular cross from the expectation on the basis of average GCA effects of the two lines involved. It is equivalent to an interaction result of a factorial experiment (Falconer and Mackay 1996; Acquah 2012).

## Diallel Design Analysis

According to Griffing (1956) there are four different methods for diallel design based on whether the parents, their reciprocal F1 crosses, or both, are included in the evaluation with the F1 crosses:

**Method I or Full Diallel Design:** The method I or full diallel design consisted by parents, one set of F1's and reciprocal F1's. The system gives  $n^2$  genotypes (Griffing 1956).

**Method II:** This method encompasses parents and one set of F1's without reciprocal F1's. This design gives  $n(n+1)/2$  genotypes.

**Method III:** Here, one set of F1's and the reciprocals are investigated. This design provides

the equation  $a = n(n - 1)$  different number of genotypes.

**Method IV:** Here, it only includes F1 crosses. This design provides the equation  $a = n(n - 1)/2$  different number of genotypes.

## Application

- The DD study estimates the genetic makeup of variation of a quantitative character.
- It also estimates the combining efficacies of different inbred lines involved in the cross.
- A random model involves parents that are random members of a random mating population.
- A random model is useful for estimating GCA and SCA variances. These effects only apply to the set of parents in the diallel.
- It is also widely used for developing breeding populations for recurrent selection (Acquaah 2012). In addition, Johnson and King (1998) reported that diallel mating designs are deployed to provide the maximum opportunity to manage coancestry in breeding population and maximize selection differential.

## Drawbacks

- The diallel design is the most mislead of all mating designs as acquired from various genetic information (Hallauer et al. 2010). Much of its limitation might be due to the presence of two models for its analysis, i.e., one is random and other is fixed (Griffing 1956).
- In reality, a diallel design with self and reciprocals is neither practical nor it is sustainable for utility.
- In extensive mating patterns, the number of parents that can be bred this way is limited (Johnson and King 1998).

## Concluding Remarks

These kinds of experimental studies may not provide a conclusive statement on the effects of non-independent distribution of gene patterns in the parents. The diallel mating design should only be

used to evaluate genetic variance components when the parents of the diallel have been randomly selected from a population subjected to linkage equilibrium.

## Dian Fossey

Crickette Sanz<sup>1</sup> and David Morgan<sup>2</sup>

<sup>1</sup>Washington University in St. Louis, Saint Louis, MO, USA

<sup>2</sup>Lester E. Fisher Center for the Study and Conservation of Apes, Chicago, IL, USA

## Introduction

Dian Fossey (January 16, 1932, to December 26, 1985) was an American primatologist who dedicated her career to studying and conserving

mountain gorillas (*Gorilla beringei ssp. beringei*). In 1967, she established a research site at Karisoke in the Virunga Mountains of Rwanda to study mountain gorillas. Karisoke is currently the longest running field study of wild gorillas and internationally recognized for its scientific outputs and conservation efforts.

## Early Years

During her first trip to Africa in 1963, Fossey visited Olduvai Gorge and met Louis Leakey. Leakey's descriptions of Jane Goodall's pioneering studies of wild chimpanzees at Gombe intrigued Fossey and left a lasting impression. From Olduvai, Fossey traveled to the site where George Schaller had conducted a study of mountain gorillas at Mt. Mikeno in Democratic Republic Congo (then Zaire). In 1966, Fossey returned to Africa and traveled to Mt. Mikeno with the aim of establishing a research project focused on mountain gorillas. She would eventually identify and habituate several groups of gorillas in the Kabara Region. Fossey was also making progress documenting the behavior of the mountain gorillas when she was evacuated to Uganda due to political unrest in Congo. Not to be deterred from her study of mountain gorillas, Fossey would establish the Karisoke Research Center in the Rwandan portion of the Virunga Mountains in 1967.

## Research Contributions

Fossey obtained her doctoral degree in animal behavior from Cambridge University under the supervision of Dr. Robert Hinde (Fossey 1976) and would make several seminal contributions to understanding gorilla behavior and ecology throughout her academic career. She published many of the first reports of mountain gorilla behavior, including descriptions of their ranging (Fossey 1974), reproduction (Fossey 1982), vocalizations (Fossey 1972), feeding (Fossey and Harcourt 1977), male emigration and female transfer (Harcourt et al. 1976), and ontogeny

(Fossey 1979). Many of these publications continue to be relevant and are cited by current publications. Through her popular writings, she was very effective in sharing the rich social lives and individual personalities of the mountain gorillas with not only the academic community but to a large public audience. Fossey was a visiting associate professor at Cornell University while writing a book entitled "*Gorillas in the Mist*" (Fossey 1983) which remains one of the most widely read books about gorilla behavior. This book provides remarkable insights not only into the daily lives of mountain gorillas but also a riveting first-hand account of the challenging field research conditions and conservation context in which Fossey worked.

## Conservation

Throughout her 20 years studying gorillas in the wild, Fossey was increasingly confronted by the myriad of threats to gorilla survival. The impacts of poaching, the pet trade, and habitat destruction were devastating gorilla populations in the Virunga Mountains and beyond (Harcourt and Fossey 1981). Fossey was outspoken in her conservation efforts, but her "active conservation" tactics were controversial and often aggressive to local people. In December 1977, a male gorilla named "Digit" who Fossey had known for many years was killed by poachers when defending his group. He was speared several times before succumbing to his wounds, which provided time for his family group to flee. This would prompt Fossey to launch the "Digit Fund" to raise funds for conservation and antipoaching efforts in the region. The Digit Fund would later be renamed the Dian Fossey Gorilla Fund International.

## Conclusion

Dian Fossey's murder shocked the world and the identity of her assailant still remains unknown. Although her personal contributions were cut short by an untimely death, there is no doubt that

her research and conservation efforts have had a lasting impact on generations of aspiring scientists and improve the survival prospects of wild apes. The Karisoke Research Center is internationally renowned for its research and continued vigilance of the dwindling numbers of mountain gorillas in the Virungas. The Dian Fossey Gorilla Fund International has been extremely successful in raising awareness about the plight of wild gorillas and also supports the conservation of many populations of wild gorillas.

## Diathesis Stress

Reema Chaudhary

Molecular Biology Division, Bhabha Atomic Research Centre, HBNI, Mumbai, India

## Definition

The diathesis stress is a psychological theory which relates diathesis (susceptibility) and stress in order to develop psychopathological disorder.

## Stress

Stress is a psychological state marked by imbalance in the psych functioning of mind resulting from “unfavorable” or “not desirable” circumstances. Stress is linked to several psychopathological disorders and even considered as a major etiological factor for their occurrence. Different models have been suggested which aim to draw the relationship between the stress level and occurrence and degree of the disorder, which also depends on the individual’s psychological and biological characteristics. The majority of individuals suffering from depression must have been the victim of severe stress in the immediate past, where as some individuals after facing extreme stress do not show any trait of depression.

Some people who have experienced the stress but do not develop a disorder suggest that susceptibility is an important component of psychopathology.

## Diathesis

The terms “diathesis and susceptibility” are used interchangeably, which mean predisposed factors making an individual susceptible to the

development of disorder. The factors could be biological or psychological.

Ingram et al. (1998) suggested that diathesis is a trait which is *stable* but can change, and is usually latent and *endogenous* to the individual.

- Stability does not mean permanence, as the concept of therapy is sprouted from the possibility that positive alteration in a stable variable may occur and revert to the normal condition.
- Endogenous to the person means whether arising due to biological or psychological factors, but resides within the person. So this differentiates diathesis from external factors such as stress. But it may require some sort of activation (external factor; stress) to develop the disordered state, pointing to the feature of latency.

## Diathesis Stress Models

### Dichotomous Diathesis Model

Dichotomous diathesis describes that if there is no diathesis, not even severe stress can lead to the development of the disorder whereas, when it is present, occurrence of disorder depends on the level of stress (Fig. 1).

### Quasi-Continuous Diathesis Model

In this model, it is said that once the threshold for diathesis is crossed, the continuous effect of diathesis is seen, thus it is called as quasi-continuous, though minimal level of diathesis may not result in the disorder even after facing high stress.

### Threshold Model

The synergistic effect of diathesis and stress results in an effect beyond their combined separate effects, which is termed as threshold model.

With the increase in the intensity of the trauma, the risk for psychopathology also aggravates. So, the threshold which decides the occurrence of the disorder is different for every individual (Monroe and Simons 1991).

### Risk-Resilience Continuum Model

Invulnerability, competence, protective factors, and resilience are considered to be antonyms of diathesis or susceptibility. These are the factors which enhance the resistance to the stressors. They may include personality traits, social skills, environment, and coping style.

### Schizophrenia: A Neural Diathesis-Stress Model

This model mainly proposes that stress affecting the neural system may lead to the onset and/or

**Diathesis Stress, Fig. 1** Different proposed Diathesis-models

worsen the symptoms of schizophrenia in susceptible individuals.

Schizophrenia is a serious neurodevelopmental disorder in which the person has the difficulty in distinguishing real and virtual world. Stress and schizophrenia have been linked since many years. Stress responsivity in schizophrenic individuals is addressed at two levels:

1. Behavioral
2. Biological

#### Behavioral Response

The occurrence of stressful events contributes in worsening of schizophrenic symptoms, suggesting a relationship between the two. The exposure to stressors can exacerbate premorbid behavioral dysfunction or may fasten the onset of first episode of psychosis (FEP).

Children with high risks for schizophrenia (parents are schizophrenic) show greater behavioral dysfunction, if parenting has not been proper in their developing days. The adoption studies have revealed that the amplitude of worsened schizophrenic symptoms increased in the biological offspring of schizophrenic parents whose upbringing is done in dysfunctional adoptive family (Tienari 1991).

The above findings focus on the effects of psychosocial stressors on the symptoms of schizophrenia, but there is an interactive effect of stressors and susceptibility. High-risk children (high diathesis) are susceptible to manifest the disorder than the controls on exposure to parental maltreatment. The probability of occurrence of schizophrenia is increased in offspring of women who have experienced severely stressed events (e.g., death of a spouse during pregnancy) (Huttunen 1989). These events interfere with normal functioning of the HPA (Hypothalamic-Pituitary-Adrenal) axis which results in the impairment of neurological system.

#### Biological Response

##### 1. *The HPA Axis*

There are various neurological systems which can be activated by the stressful events, but significant among them are the

**Diathesis Stress, Fig. 2** The schematic diagram of (Hypothalamic-Pituitary-Adrenal) HPA axis

sympathoadrenal medullary system (SAM) and HPA axis (Fig. 2) (Joëls and Baram 2009), which release some secretagogues (neurotransmitters, enzymes, and hormones) that help in maintaining homeostasis and have the ability to alter brain function.

The periventricular nucleus of the hypothalamus releases CRH (corticotropin releasing hormone) under the influence of stressful stimuli which in turn stimulates the pituitary to release ACTH (adrenocorticotropin releasing hormone). This activates the adrenal glands to release glucocorticoids, cortisol being the prominent one in primates and corticosterone in rodents. Brain has the receptors for glucocorticoids, which regulates the levels of these hormones through negative-feedback check. The levels of glucocorticoids need to be maintained, their hypersecretion or poor negative feedback regulation can affect the brain functions and behavior adversely. The presence of CRH receptors in the cortical region of the brain, which includes locus coeruleus, the periventricular nucleus of the hypothalamus, the bed nucleus of the stria terminalis (BNST), and the central nucleus of the amygdala, can lead to free-forward activation resulting in allostasis.

The effects of exposure to stressors can be addressed by measuring the glucocorticoids in cerebrospinal fluid (CSF) plasma, urine, or saliva. The HPA axis function is examined using two indices among psychotic patients and high-risk individuals:

- I. Baseline cortisol
- II. The cortisol awakening response

#### *Baseline Cortisol*

The term “baseline” refers to the initial measurement of a variable in the absence of any exposure. Recent studies indicated elevated plasma/serum cortisol levels among people experiencing the first episode of psychosis (FEP) (Dogan Bulut et al. 2016).

#### *The Cortisol Awakening Response (CAR)*

It is an increase in the cortisol levels which occurs after awakening in the morning in some people. The reason is not known, but it might be linked to the preparation of the HPA axis. Though no strong finding has been reported till now, but in some cases, a blunted CAR among FEP has been observed (Mondelli et al. 2010).

Genetic and environmental (stressors) factors both act in isolation or synergistically in dysregulation of the HPA axis. For example, serotonin transporter gene (Caspi et al. 2010), FKBP5 gene (Klengel et al. 2013), and the glucocorticoid receptor gene (also called

NR3C1) are involved in modulation of the HPA axis following stressful events.

## 2. *Structural Abnormalities*

### *Hippocampus Abnormalities in Schizophrenia*

The volume of hippocampal region is reduced in schizophrenic patients, suggesting the dysfunctioning of the HPA axis.

## 3. *Dopamine Activity*

An increase in dopamine (DA) release and synthesis have been observed in psychotic patients in response to stressors (Howes et al. 2012). Dopamine has been positively related with worsening of symptoms (hallucinations and delusions) and possibility of relapse in psychosis. The varying magnitude of stress modulates the HPA axis, resulting in the cortisol release which in turn enhances the DA receptor densities as well as DA release. This suggests that it can also be viewed as a moderator of the expression of the diathesis.

To summarize, the degree of the association between diathesis and psychiatric outcome may alter on the basis of the varying level of the HPA axis activation or sensitization. Thus neural diathesis-stress model (Fig. 3) focuses on both diathesis as one factor and biological and behavioral changes due to stress as another factor.

**Diathesis Stress, Fig. 3** The neural diathesis-stress model

## Conclusion

The several diathesis models aim to draw the relationship between the external stressor and the individual which actually varies according to the person and the degree of stress. The individual who is vulnerable is more prone to develop the disorder than the control one. Not only external factors play a role in the onset of psychotic symptoms, but also the neurological system leads a pivotal role. The neural diathesis-model of schizophrenia proposes that stress, through the effect of cortisol production which further affects downstream processes, in turn, results in developing or worsening of psychopathological symptoms. But susceptibility or diatheses is an important etiological factor in the development of the disorder.

## Dichotomous Stress

Vikas Pareek

Computational Neuroscience and Neuroimaging Division, National Brain Research Centre (NBRC), Manesar, Haryana, India

## Synonyms

[Stress dichotomy](#)

## Definition

Dichotomous stress represents bidirectional effect (+/–) of stress in various biophysical and biochemical responses and thus the behavioral outcome of an animal under the presence of stressors.

## Introduction

Mechanism of homeostasis is the key by which an organism maintains its integrity, i.e., it helps in maintaining the constant internal milieu irrespective of variant environmental influences (Goldstein 2013). Firstly, used by Selye, H., in 1956, the word “Stress” describes the physiological condition of an organism in presence of stressors (element causing the threat to homeostasis, can either be the psychosocial or the physical agent) leading to functional outcome termed as “Stress Response” (Selye 1956). Three major neuroendocrine systems which majorly mediate components of stress response are Hypothalamus-Pituitary Axis (HPA axis), Sympathomedullary Axis, and several other modulatory peptides like, Orexin-A, Ghrelin, etc.

Under different conditions of stress and respective physiological and psychological status of the subject, different patterns of biological responses are displayed by the animals termed as, “Situational Stereotypy.” Based on the severity of situations animals tend to choose from two states of responses whether it be, “Aversive Vigilance” or the “Active Coping.” Numerous studies on animal models have shown that different individuals behave differently in presence of stressors and this has been linked to the differences in their genetic makeup, defined under a term “Response Stereotypy” (Lacey and Lacey 1958; Lacey 1967). Heritability ( $h^2$ ) considering role of both the environment as well as genetic makeup of an organism defines well the stereotypy in behavior shown by the individuals.

Stress responses are just not unidirectional when linked with their net outcome, whether as behavioral changes (eating behavior), psychopathologies (suicidal tendency), or the degenerative pathologies (anovulation, muscular atrophies, etc.). Stress dichotomy represents the duality shown by stress whether by the different scales of stress or due to the interaction between stress and the preexisting internal status of an organism, biophysically, biochemically, as well as psychologically.

## Obesity and the Stress Dichotomy

Stress has the dichotomous effect on the energy balance of the body. Adaptive thermogenesis and Brown Adipose Tissues (BAT) supports the dual nature of stress, explaining its effect, considering obesity versus weight loss/obesity resistance. In presence of chronic stress, individuals have different outcomes, stress-induced obesity has been shown linked with the interaction of stress-hyperphagia-unchanged BAT, while considering obesity resistance the stress-hypophagia/hyperphagia + BAT recruitment-enhanced thermogenesis is inferred. This duality in nature of stress considering physiological conditions of an animal presents the inferences explaining the interaction between psychological/physical stress with the physiological involvement of moieties. Semantically psychogenic and metabolic stressors are different but they present themselves as two sides of the same coin (Bartolomucci and Razzoli 2016).

Little stress has been observed to engender a compensatory increase in appetite, but the severe stress has usually been studied resulting, anorexia. This represents the dual nature of an acute stress for the behavioral outcome on the basis of stress's severity (Yau and Potenza 2013).

## Acute Stress Responses Versus Chronic Stress Response

Acute stress leads to responses which are adaptive in nature, but with repeated/continuous facing of an acute stress, the stress responses will become maladaptive. In the acute stress conditions, stress hormones promote the dispersal of an energy store for their immediate use, site-specific allocation of the energy and activation of immune system thus helps to maintain an internal milieu. In the case of chronic stress, e.g., chronic sympathetic nervous system (SNS) activation leads to vascular hypertrophy and thus chronic rise in blood pressure (Schneiderman et al. 2005). Further elevated basal levels of stress hormones associated with chronic stress does suppress the immunity by directly affecting cytokine profiles; an increase in Th2 cytokines relative to Th1 cytokines

suppressing cellular immunity in favor of humoral immunity, Segerstrom and Miller, found that pro-inflammatory, Th1 and Th2 cytokines become dysregulated under chronic stress leading suppression of both humoral and cellular immunity (Segerstrom and Miller 2004).

## Conclusion

The dichotomous behavior of stress, in particular towards obesity, provides us with the general idea of how the psychogenic and physical stressors differentially interact with individual's physiological milieu leading to variant stress responses and behavioral outcomes/phenotypic variations. Though not yet well explored, the dichotomy in stress is required to be dealt through well explanatory electrophysiological experimentation in animals and neuroimaging studies in animals/humans for acute as well as longitudinally for the chronic stress-induced behavioral changes, psychopathologies, or the degenerative pathological conditions.

## Dictator Game

Jennifer Vonk

Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

[Prosocial choice test](#)

## Definition

The dictator game is a paradigm used in behavioral economics where an actor (sometimes labeled as donor) has the power to distribute a predetermined set of rewards among themselves and at least one recipient. Typically, the actor's choices are identical but the recipient either receives an identical reward or no reward. Unlike the ultimatum game, the recipient has no choice regarding receipt of the allocated reward.

## Introduction

Humans are unique for the extent to which they engage in prosocial behaviors that benefit others, including nonkin, at some cost to themselves (de Waal and Suchak 2010). The dictator game is a well-known tool for assessing prosocial preferences in humans (Kahneman et al. 1986; Forsythe et al. 1994). It was first adopted for use with nonhuman primates when Silk et al. (2005) presented captive chimpanzees with the

opportunity to choose between two food rewards in what has become known as the “prosocial choice task.” Each choice for the actor simultaneously delivered one of two reward options for a recipient; either the recipient received no reward (1/0) or a reward equivalent to that of the actor (1/1). This became known as the 1/1, 1/0 distribution with the first number within each pairing representing the option for the actor and the second number representing the option for the recipient.

The paradigm has been widely adopted for use with young children and various other primate species (Burkart and Rueth 2013; Claidière et al. 2015; Cronin 2012; House et al. 2012; Messer et al. 2017; Vonk et al. 2020), and even non-primates (e.g., bottlenose dolphins, Nakahara et al. 2017; domestic dogs, Dale et al. 2016; jackdaws, Schwab et al. 2012; Long-Evans rats, Hernandez-Lllement et al. 2015) with various other reward distributions being presented. It is still most commonly used with primates. The paradigm allows investigators to assess which species behave prosocially when there is little cost to themselves for doing so. That is, they receive the same reward regardless of their choice and effort, but with a little more attention, they can choose to be generous rather than selfish.

In the original version, chimpanzees pulled one of two food trays toward themselves, which simultaneously caused an attached food tray to move away from the actor toward the recipient housed in another enclosure and facing the actor (Silk et al. 2005). In a follow-up study, a bar-pull apparatus was instead used so that actor chimpanzees could choose a top or bottom tray to pull, which distributed food to themselves and a recipient housed in an adjacent (rather than opposing) enclosure. Importantly, “no recipient” trials were interspersed with “recipient” trials to provide a comparison of “prosocial” choices when there was a recipient to benefit and when there was not. This manipulation allowed experimenters to differentiate between ostensive prosocial behavior that was not motivated by prosocial concerns because the actor could simply be demonstrating a bias to choose the option that contained the greater amount of food, possibly without the

realization that the reward earmarked for the recipient was inaccessible. Unfortunately, not all studies using the dictator game have implemented a “no recipient” condition, but it is critical to understanding the underlying motivations of the subjects.

In most dictator game studies with nonhumans, the actor and recipient exchange roles over the course of the study so that researchers can keep track of whether they tend to exchange rewards more frequently with individuals that behave prosocially towards them. This can be done in a “contingent choice” protocol where the actor and recipient trade roles on each trial (Brosnan et al. 2009), but this is more challenging to implement. Brosnan and colleagues found no evidence that chimpanzees behaved reciprocally in such a setup. Yamamoto and Tanaka (2010) obtained similar null results even when testing mothers and offspring. Of course, it is possible that chimpanzees reciprocate across other contexts outside of the experiment, as in allogrooming and tolerated theft. A review of prosocial choice tests in primates revealed that primates tended to attend to dominance relations although some species shared up the hierarchy whereas others tended to share down the hierarchy (Cronin 2012).

Initially, results of the tests suggested that non-human primates were not predisposed to behave prosocially. Although they seemed largely unconcerned with whether recipients received rewards even when recipients protested loudly and begged for food (Silk et al. 2005; Vonk et al. 2008), chimpanzees did not appear to behave spitefully by choosing to remove food rewards from recipients when given the opportunity to do so (Jensen et al. 2006). In these studies, chimpanzees appeared sensitive only to their own rewards. They appeared indifferent to outcomes that either benefited or were detrimental to conspecifics. However, studies began to reveal some suggestive evidence for prosocial motivations in other primates (long-tailed macaques, Massen et al. 2011), especially cooperative breeding primates, such as common marmosets (Burkart et al. 2007) and brown capuchins (Brosnan et al. 2009; Claidière et al. 2015; de Waal et al. 2008; Lakshminarayanan and Santos 2008; Suchak and

de Waal 2012; Takimoto et al. 2010). Capuchins behaved prosocially specifically when there was no reward for themselves and their choices determined only whether a recipient would receive a reward or not using a 0/1, 0/0 distribution (Lakshminarayanan and Santos 2008). On the other hand, tamarins have not always behaved prosocially (Cronin et al. 2009). Even chimpanzees appeared more likely to distribute rewards to recipients when they could not view the food rewards (Horner et al. 2011) and when tokens were presented to represent food choices rather than having actors directly work to procure the food. However, obscuring the visibility of the food and allowing actors to consume their own rewards before making an additional decision to offer a reward to a conspecific did not result in prosocial behaviors in an “extinction task” variant. In fact, chimpanzees declined to make the “prosocial” response more quickly when recipients were present versus absent (Vonk et al. 2008). It is important to note that the lack of prosocial choices in prosocial choice tests occurs even when actors and recipients are close associates and engage in otherwise affiliative behaviors, such as allogrooming. Therefore, it has been difficult to identify consistent factors predicting prosocial responses in prosocial choice tests.

Follow-ups to the original studies manipulated the quality and amount of the available rewards, asking whether actors could distinguish between preferred and less preferred rewards. Importantly, some studies manipulated the status of the recipient although it would be most important to demonstrate that actors attended to need states such that they were more generous to those that could most benefit from their actions (Liebal et al. 2014). Fewer studies have focused on the relationships between actors and recipients in these studies. Mendonca et al. (2018) tested mother-offspring chimpanzee dyads using a touchscreen version of the task and five of these six chimpanzee mothers made prosocial choices. However, another study failed to find evidence of prosocial food choices between mother and offspring chimpanzees (Yamamoto and Tanaka 2010). Another exception allowed a female orangutan to behave prosocially toward her sister or her

mother or to both simultaneously using tokens that represented various options (Emigh et al. 2020). The orangutan appeared to choose differently depending on who was able to benefit from her choices, and often behaved prosocially. Unfortunately, due to constraints in the testing environment, the “no recipient” condition was not presented to clarify the motivations for her choices or her comprehension of the options.

It is interesting, however, that orangutans, deemed the least socially oriented of the great apes, have demonstrated prosocial preferences in other studies (Amici et al. 2014b) whereas the more gregarious chimpanzees, gorillas, and bonobos have not typically behaved in a prosocial manner (Amici et al. 2014a; Tan et al. 2015). Of course, orangutans have not always behaved prosocially in such studies either (Kim et al. 2015). Furthermore, bonobos and chimpanzees have demonstrated somewhat inconsistent preferences across studies (Amici et al. 2014a, 2014b; Liebal et al. 2014; Pelé et al. 2009; Tan and Hare 2013; Tan et al. 2015). It is recognized that the dictator game may not be the “acid test” of prosocial preferences in nonhumans (Marshall-Pescini et al. 2016), with the escape and instrumental helping paradigms potentially more likely to elicit demonstrations of concern for others’ welfare. Sometimes subtle aspects of the testing methodology appear to influence the pattern of results (Dale et al. 2016), making it yet unknown the exact mechanisms that control choices in such tasks.

## Conclusion

The dictator game has proven to be an incredibly useful and flexible tool for probing prosocial preferences, particularly in primates, at least within the context of food provision. Despite some challenges with the methodology, the task has provided a framework for exploring prosociality in nonhumans – a topic that was once considered unworthy of study due to the belief that prosocial preferences were unique to humans. Since its extension to nonhuman primates (Silk et al. 2005), comparative research into prosocial

preferences has exploded. Although the prosocial choice task has been extended for use in other species, its utility has not been fully exhausted.

## Definition

**Diffusion** is derived from the word of *Latin* origin, *diffundere*, meaning “to spread way out.” It is a physical process involving the net movement of molecules (solute) from a region of its high concentration to lower concentration. The process whereby the spontaneous movement of the particles of liquids, gases, or solids causes them to intermingle and spread uniformly throughout a region of higher concentration to one of lower concentration. It can involve either the spreading of a material through a medium or the transport of a particle across a membrane.

## Explanation of Diffusion in the Context of Different Disciplines

The concept of diffusion is widely used in: physics, chemistry, biology, sociology, economics, and finance (diffusion of people, ideas, and of price values). However, in each one of them, the object

(e.g., atom, idea, etc.) that is undergoing diffusion is “spreading out” from a point or location at which there is a higher concentration of that object to the region where it is in low concentration.

There are two ways to introduce the notion of *diffusion*: either a phenomenological approach starting with Fick’s laws of diffusion and their mathematical consequences, or a physical and atomistic one, by considering the *random walk of the diffusing particles*.

In the phenomenological approach, according to Fick’s laws, *diffusion is the movement of a substance from a region of high concentration to a region of low concentration without bulk motion* (Philibert 2009).

From the *atomistic point of view*, diffusion is considered as a result of the random walk of the diffusing particles. In molecular diffusion, the moving molecules are self-propelled by thermal energy. Random walk of small particles in suspension in a fluid was discovered in 1827 by Robert Brown. The theory of the Brownian motion and the atomistic backgrounds of diffusion were developed by Albert Einstein (Mehrer and Stolwijk 2005).

## Aim of Diffusion

Diffusion occurs with the aim of reaching to a state of equilibrium. Equilibrium is when the amount of the particles is the same throughout a solution or is dispersed equally through a given area.

## Factors that Affect Diffusion

Diffusion is altered by the temperature, distance travelled, area of interaction, and particle size. Each of these factors, independently and collectively, can change the extent and rate of diffusion.

## Temperature

In any system, particles are moving with a certain amount of kinetic energy. This movement of molecules can appear random. It is usually not directed in any particular manner. When these particles collide with one another, there is a

change in the direction of their movement as well as momentum and velocity. With an increase in temperature, the kinetic energy of all particles in the system increases. This increases the rate at which all the molecules (both solute and solvent) move, increases their collisions with one another, thus, increasing their diffusion rate.

### Area of Interaction

Increase in the area of interaction increases the rate of diffusion. For example, this factor can be observed even better if the gas has an odor or color. When they are confined to the smaller surface area within the crucible, the rate of diffusion remains low as compared to when they are in larger surface area, indicating that molecules diffuse better when the area of interaction increases.

### Particle Size

Depending on the mass of the molecules and its surface area, at any given temperature, the diffusion of a smaller particle will be more rapid than that of a larger-sized molecule. A heavier molecule with a larger surface area will diffuse slowly, while smaller and lighter particles will diffuse more quickly.

### Role of Diffusion

Diffusion is an important part of many biological and chemical processes. In biological systems, diffusion occurs at every moment, across lipid bilayer membranes in every cell as well as through the body. Some examples are given below:

1. Gaseous Exchange: Respiration produces waste carbon dioxide, causing the amount of carbon dioxide to increase in the cell such that eventually

its concentration in the cell is higher than that in the surrounding blood. The carbon dioxide then diffuses out through the cell membrane and into the blood (Spaeth and Friedlander 1967).

2. Nerve Impulses: Neurons communicate with other cells by sending electrical signals along their cell membrane. At rest, the inside of the neuron's membrane is negatively charged, while the outside is positively charged. An electrical signal is generated when the membrane lets ions from outside flow into the cell. This inflow changes the charge on the inside of the membrane from negative to positive. This switch in charge is an electrical signal that moves down the length of a neuron's arm. The movement of ions is guided by diffusion (Bromberg and Dill 2002).
3. Olfaction: The chemical senses of olfaction and taste such as the detection of hazards, pheromones, and food are very different from vision and hearing, which detect the energy of different wavelengths in the form of light and sound. Chemical senses rely on the physical movement of molecules from the signaler to the sense organ of the receiving animal. This requires either diffusion or flow of currents (Wyatt 2014).
4. Digestion: Diffusion helps in the absorption of digested food materials in the alimentary canal. End products of digestion such as amino acids and glucose diffuse through facilitated diffusion with the help of transporters across the wall of the ileum into the blood for transport to other parts of the animal body.

### Conclusion

Diffusion in the animal body is necessary as it is a feature of number of processes which control and

supply vital substances to the body in order for basic survival. As already noted above, it is important for the absorption of digested nutrients, gas exchange, and the propagation of nerve impulses, the movement of hormones, and other metabolites towards their target organ and for nearly every event in embryonic development.

## Definition

Experimentally controlled innovations in behavior are seeded into groups of individuals, and the spread (or otherwise) of the innovation is tracked and documented (Whiten and Mesoudi 2008).

## Introduction

One of the most famous examples of a new behavior spreading through a group of animals is undoubtedly the case of tits in England opening milk bottle left on doorsteps. The first reports came in around 1921 in the south of England that tits would flip or pierce open the aluminum cap of milk bottle to drink the cream on top. Many years later this behavior was reported all over England, Wales, Scotland, and continental Europe, in multiple species of birds (Fisher and Hinde 1949; Lefebvre 1995; Aplin 2013b). Another famous example of the diffusion of a novel behavior is the potato and wheat washing of Japanese macaques living on an island off the coast of south-east Japan. Researchers fed the monkeys with sweet potatoes on a beach of the island regularly to habituate them to human presence and to observe them more readily. A young female started to wash sand-covered sweet potato pieces in a stream on the beach before eating them. In this case too, several years later, what had started as the spontaneous behavior of a young female had spread widely within the group (Kawai 1965; Hirata et al. 1987). Regardless of the mechanisms involved in their spread – and the debates taking place among scientists about them – these novel behaviors were adopted by new individuals through specific pathways. In other words, the diffusion patterns of these behaviors were nonrandom.

The spread and persistence of these behaviors in local populations, as well as the manifestation of variation across individuals in their performance, indicated that animals could display elements of culture and tradition (Whiten and van Schaik 2007; Hoppitt and Laland 2008; Galef 2012). Since these seminal studies, an overwhelming amount of research in a great variety

of taxa has shown that animals can acquire and use novel information to modify their behavior and guide their decisions pertaining to exploiting their environment, be it social or ecological (Laland 2004; Kendal et al. 2005; Galef 2012; Hoppitt and Laland 2013; Whiten et al. 2016). This capability is often called social learning, as opposed to asocial learning, which relies on trial-and-error learning or self-exploration and experimentation of the surrounding environment. More broadly, the behaviors learned from conspecifics are said to be transmitted socially.

A fundamental development in the field of animal social learning involves diffusion studies, which aim to characterize diffusion patterns of socially transmitted behaviors within a group or aggregation of individuals (Whiten and Mesoudi 2008; Whiten et al. 2016; Duboscq et al. 2016). Typically, diffusion studies are experimental: new behaviors – “controlled innovations” – are seeded into groups of naïve individuals, for instance, an individual model is made to learn a new behavior, and other individuals are given opportunities to observe her performing the new behavior. Innovations can also be observed spontaneously in wild animals, and long-term field studies have allowed researchers to track the diffusion of novel behaviors over generations of animals and in multiple contexts (mating, foraging, social). The aim is then to track the progressive acquisition of the new behavior in terms of pathways (from whom to whom), speed, or accuracy while investigating the characteristics of individuals/pairs/groups involved as compared to controls or variants (Whiten and Mesoudi 2008; Whiten et al. 2016; Duboscq et al. 2016). For instance, transmission pathways can be characterized as vertical if the information is transmitted from parent to offspring, horizontal if it is from peer to peer, or oblique if it is from a non-kin adult to a young. Through this paradigm, social diffusion of novel behaviors has been linked to environmental or living conditions, individual features, and social characteristics (Morand-Ferron et al. 2010; Dukas and Ratcliffe 2009). For instance, in a feeding context, bumblebees (*Bombus impatiens*) choose the same-colored flowers as those chosen by

conspecifics (e.g., Leadbeater and Chittka 2005). In a social context, client fish (*Scolopsis bilineatus*) spend more time near cooperative cleaner fish (*Labroides dimidiatus*) than cleaner fish of unknown cooperative level (e.g., Bshary and Grutter 2006). In a breeding context, flycatchers (*Ficedula albicollis*) use others’ breeding outcomes (offspring quantity and/or quality) to select a breeding habitat (e.g., Doligez et al. 2002) (see Whiten and Mesoudi 2008; Whiten et al. 2016; Duboscq et al. 2016 for other examples).

## Social Diffusion and Environmental Conditions

Sometimes, whether or not a behavior is transmitted from an individual to another has little to do with the capacities animals have or with the task at hand. It can instead be linked to whether or not acquiring the new behavior is relevant in a given context (see below). For instance, in the wild, keas (*Nestor notabilis*) failed to perform a novel task although they had the opportunity to observe a knowledgeable individual and to engage with the experimental apparatus. In captivity however, most birds solved the task after observing a proficient model (Huber et al. 2001; Gajdon et al. 2004). Similarly, spotted hyenas (*Crocuta crocuta*) in captivity solved foraging tasks better than those in the wild (Benson-Amram et al. 2013). In contrast, a novel foraging behavior (piercing a lid to access food) spreads more quickly among groups of free-ranging urban pigeons (*Columba livia*) than among captive groups (Lefebvre 1986). In natural settings too, novel behavior might fail to percolate through a group even when opportunities for social learning exist, as seen in dental flossing in Japanese macaques, for instance (Leca et al. 2010). The lack of diffusion of a novel behavior might have to do with the value of the social information provided, the relevance of the task proposed, the degree of necessity for innovation, or social, cognitive, or physical constraints, among others (Duboscq et al. 2016; Rieucan and Giraldeau 2009; Giraldeau et al. 2002).

## Social Diffusion and Individual Features

Because each individual has its own experience and personality, numerous studies have looked at the characteristics of proficient and naïve individuals and their influence on diffusion processes. In blue tits, naïve young females and subordinate males with higher problem-solving abilities were more likely to solve the novel task than others, showing that sex, age, and personality are important factors for acquiring and using social information and hence for its diffusion (Aplin et al. 2013a). Sometimes, the diffusion depends on the proficient individual's features instead: in vervet monkeys, social transmission is mostly dependent on kin relationships, i.e., it occurs vertically, from mother to offspring (van de Waal et al. 2014). But, when transmission is horizontal or oblique, individuals are also more likely to copy the new foraging technique of an adult female compared to an adult or subadult male (van de Waal et al. 2010). Similarly, monkeys do pay more visually attention to higher-ranking individuals than to lower-ranking individuals (e.g., McNelis and Boatright-Horowitz 1998; Deaner et al. 2005) and to strong affiliates compared to average affiliates (Bonnie and de Waal 2006; Micheletta and Waller 2012). This preferential attention to a particular proficient model is attached to its experience, reputation, or social tolerance (Nicol and Pope 1999; De Waal 2008; Schwab et al. 2008). Nevertheless, the best innovators, i.e., the individuals that are more likely to start using a novel behavior, are not necessarily the best models. For example, male canaries (*Serinus canaria*) were better at solving a foraging task than females, but they were also highly intolerant of other individuals in proximity, and their higher aggressive tendencies prevented them from being good models (Cadieu et al. 2010).

## Social Diffusion and Social Characteristics

Animals living in groups or aggregations do not interact randomly with one another; they have

preferred associates or affiliates. The structure of the social network of the group/aggregation – and thereby the diffusion of information between individuals – is thus heterogeneous and nonrandom (Krause et al. 2009; Croft et al. 2008). Particularly, so-called central individuals in a social network – those that are more social and/or interact with more partners than others – are seen as more influential in social diffusion processes. Social diffusion is therefore more likely to occur along “lines of affiliation” (Galef 1992). The development of network-based diffusion analysis and modeling has allowed great progress to be made in tackling underlying decision rules and transmission pathways (Franz and Nunn 2009; Hoppitt 2010) in, for instance, directed social learning, in which information is transmitted at different rates depending on association patterns between individuals (Coussi-Korbel and Fragaszy 1995). Humpback whales (*Megaptera novaeangliae*) summering in the Gulf of Maine were 6 to 23 times more likely to use the lobtail feeding technique when in association with other individuals compared to cases where there would be no or little association, which overwhelmingly supported social diffusion (Allen et al. 2013). In tits, the successful discovery of new food patches was linked to individual centrality in the flock association network: more central individuals were more likely to locate and use novel foraging patches than those with limited social connections (Aplin et al. 2012). In contrast, a simulation study showed that information spreads faster in well-mixed groups compared to more structured groups (Voelkl and Noë 2008). In structured social networks, information also spreads faster when the frequency of interactions was either disregarded (unweighted or topological networks) or distributed randomly among interacting individuals (Voelkl and Noë 2008). This shows that sociality itself has costs and benefits regarding information diffusion: on the one hand, being social greatly enhances one's potential to adapt faster and/or better to its environment; on the other hand, it might also either exclude individuals from innovation or induce individuals to adopt nonadaptive behavior by getting little or incorrect information.

## Other Fields of Diffusion Studies

Other fields have used diffusion studies to track transmission patterns and pathways, notably epidemiology and health but also cognition. A diffusion model paradigm has recently been applied to a wide range of cognitive processes related to decision-making (Ratcliff 2016), social perception (Parkinson et al. 2017), and neuron connectivity (Basset and Mattar 2017). In the latter field, so-called functional brain networks or structural brain networks can be built by considering connections between brain regions, either through, e.g., their functional connectivity or through, e.g., white matter tracts. Both network types can then be used in the investigation of intrinsic and task-evoked neurophysiological processes or baseline function and its adaptability in response to task demands, for example (Basset and Mattar 2017).

In epidemiological studies, the equation computing the diffusion patterns of socially transmitted parasites and pathogens among hosts has recently incorporated the chance that a contact opportunity between hosts occurs. This parameter takes into account with whom each individual is in contact as well as how frequently and is given by a network of contacts or proximities or space/resource sharing (Godfrey 2013; Craft 2015; Schmidt-Hempel 2017). Network epidemiology thus uses social patterns to infer potential transmission routes and can provide key insights into how parasites spread through a host population (Rushmore et al. 2017). In Japanese macaques, *Macaca fuscata*, high-ranking adult females, which were also more central in their social network, showed higher fecal gastrointestinal parasite egg counts than lower-ranking less central females. In males too, differences in sociality between fully grown adult males well integrated in their social group and young males often roaming away from social groups paralleled differences in fecal egg counts, the former showing higher latent parasitism than the latter (MacIntosh 2014). A mathematical model investigating patterns of infection transmission in Japanese macaques also revealed that infection would spread faster and to a larger number of individuals

if it started with a central individual (Romano et al. 2016).

Overall, diffusion studies are widespread and do not only concern social learning processes. Nevertheless, their development in this particular field brought about extraordinary insights into relationships between the social and ecological environment of individuals while accounting for their cognition, physiology, and behavior. Ultimately, a diffusion process is the passage of “something” from one point to another along a certain pathway. Investigating each step and characteristics of this process can help understanding how animals deal with their environment, be it social or ecological, as well as bring about insights into the evolution of sociality in all its complexity and variation.

## Digestive System

Priyanka Verma

Department of Molecular and Human Genetics,  
Banaras Hindu University, Varanasi, India

## Human digestive system

Digestive system is a group of organs, which helps in the digestion of food and absorption of macro/micronutrients. Digestion is the process in which our body breaks the complex food

material into smaller molecules via mechanical and chemical method (Pastor 1995). Human digestive system includes the: alimentary canal (mouth, pharynx, esophagus, stomach, small and large intestine, and anus) and accessory organs (teeth, tongue, salivary glands, liver, gall bladder, and pancreas) (Davenport 1966).

### Alimentary Canal Organs

**Mouth:** It is also known as oral or buccal cavity and first orifice through which body receives food and air. The primary function of mouth is food intake and helps initial digestion of food. Apart from its primary function, its structure also helps in the formation of speech. Mouth is able to produce saliva from salivary glands, which contains digestive juices and acts as a lubricant for the food. A digestive juice contains various enzymes like salivary amylase, lysozyme, kallikrein (proteases), and lingual lipase. Major functions of these enzymes are given below:

Amylase: Breaks starch into small sugar molecules

Lysozyme: Breaks lipopolysaccharide membrane of bacteria

Lipases: Breaks fatty acids

Kallikrein: Breaks proteins found throughout the body

**Pharynx (throat):** It is the cone-shaped passage-way, where the ventrally located oral cavity can pass food bolus to the dorsally located esophagus for further digestion of food while the dorsally located nasal cavity can conduct air to the ventrally located larynx and trachea for respiration.

**Esophagus:** It is the connecting tube between mouth and stomach. It is the about 25.4 cm length and which is lined by mucosal layer for the food bolus sliding via peristalsis movement.

**Stomach:** Chewed food is deposited into the “J” shaped expandable pouch known as stomach. It secretes gastric acids and digestive enzymes which aid in the digestion of food. Gastric acids contain hydrochloric acid (HCl),

potassium chloride (KCl), and sodium chloride (NaCl), which is produced by the glands present in the lining of the stomach. The pH of the gastric acid is 1.5–3.5, which helps in the activation of digestive enzyme pepsinogen into pepsin. Stomach acidity is maintained by  $H^+/K^+$ ATPase and kills the bacteria. Acidity of the stomach is maintained by bicarbonate produced by other cells of the stomach.

**Small intestine:** Small intestine is 6–7 m long, and it includes duodenum, jejunum, and ileum. Major function of small intestine is chemical digestion and absorption of nutrients.

|               |                          |                                         |
|---------------|--------------------------|-----------------------------------------|
| Proteins      | Trypsin,<br>Chymotrypsin | Smaller peptides, amino acids, peptides |
| Triglycerides | Lipases                  | Free fatty acids and Monoglycerides     |
| Carbohydrates | Amylase                  | Simple sugars and Monosaccharides       |

Digested or indigested foods are now available in the lining of small intestine for absorption of micronutrients nutrients via simple/passive diffusion, facilitated diffusion, primary active transport, or secondary active transport. Water, electrolytes, and vitamins are also absorbed by the plicae circulares of the intestine.

**Large intestine:** Large intestine is approximately 1.5 m long and 6–7 cm in diameter and absorbs basically water and micronutrients from undigested food. Major function of large intestine is conversion of undigested material into feces. It includes cecum, colon, rectum, and anal canal. It also helps in the reduction of acidity via production of bicarbonate and protection of infections via production of antibodies. Undigested waste material is transferred to the rectum in solid form known as stool. Stool basically contains undigested waste food debris and bacteria.

**Rectum and Anus:** Rectum is the chamber which connects the colon and anus. When stool or gas received in the rectum then, sensory nerves send the message to the brain. Brain decides it is defecated from the body and transferred in the anus. Anus is the last part of digestive system and approximately 2 inches long. It helps in the process of stool removal from the body.

### Accessory Organs

**Teeth:** It helps in the chewing, cutting, tearing, grinding of food before entering into the digestion. There are four types of teeth in the mouth according to their function. Incisor cuts the food like a scissor, whereas canine tears the food and molar, premolar grinds the food.

**Tongue:** Tongue helps in the mastication and swallowing the food. Tongue has four taste buds: sweet, sour, bitter, and salty flavor. A fifth taste “Umami” results from tasting monosodium glutamate.

**Salivary glands:** It produces saliva, which keeps the mouth and food moist.

**Liver:** It is the largest gland and has excellent regeneration property. Liver has many functions such as bile production, fat, protein, and carbohydrate metabolism, adsorption and metabolizing of bilirubin, vitamin and mineral storage. It also helps in blood filtration and performs some immunological function such as clearing of foreign particles in the gut (Yen 2001).

**Gall bladder:** It stores and concentrates the bile which helps in the emulsification of fatty acids.

**Pancreas:** It is also part of the digestive system. It produce insulin and glucagon, which are very important in controlling blood levels of nutrients, such as glucose and amino acids, and somatostatin, and may inhibit growth hormone secretion.

### Digestive System Process

There are seven processes which involve in the digestion of the food:

1. **Indigestion:** It is the process of food intake via swallowing or absorbing it.
2. **Propulsion:** It is the movement of chewed food into the esophagus, and it is a series of alternating contractions and relaxations of smooth muscle, which cover the inner lining of digestive organ.
3. **Secretion of digestive enzyme:** Digestive enzymes (such as renin) and other substances (e.g., digestive juices) help in the adjustment of the pH in food material and chemically break the food material.
4. **Mechanical digestion:** Chewing and muscular churning of food are the two important processes for physically breaking down food into smaller pieces. Chewing occurs in the mouth and muscular churning occurs in the stomach, small intestine.
5. **Chemical digestion:** Food is chemically breakdown into smaller pieces via enzymes present in stomach and small intestine.
6. **Absorption:** It is the process where digested food is entered into the body. It is the movement of molecules from digestive tract to adjacent vessels and blood.
7. **Defecation:** It is the process of elimination of undigested material from the body via anus.

### Digestion of Food

Digestion of food is of two types: (1) mechanical digestion via mastication and mixing of food in the buccal cavity and (2) chemical digestion via digestive enzymes (Farner 1960).

**Chemical Digestion of Food:** It is the catabolic process in which large and complex molecules are chemically breakdown into smaller ones, i.e., breakdown of covalent bond in organic molecules via digestive enzymes.

**Carbohydrate digestion** begins in the oral cavity and then stomach followed by duodenum along with small intestine via various digestive enzymes. Large polysaccharide chains such as starch and glycogen is first digested by salivary amylase into disaccharides. Some polysaccharides, disaccharides are digested by gastric amylase, gelatinase, and pancreatic amylase. In the intestine, covalent bond of disaccharides for conversion of monosaccharide is breakdown via different types of enzymes like sucrase, lactase, maltase, and isomaltase.

**Protein digestion** begins in the stomach, pancreas, then followed by intestine. Proteins are large and complex polypeptide chain of amino acids, which are breakdown by pepsin, trypsin, chymotrypsin carboxypeptidase, aminopeptidase, and peptidase.

**Lipids digestion** is same as the protein digestion like it starts in the stomach, pancreas, then

followed by intestine. Lingual and gastric lipases, lipase, esterase are the digestive enzymes, which breaks lipids into glycerol and fatty acids.

**Nucleic acid** is converted into pentose sugars, N-containing bases, and phosphate ions via pancreatic ribonucleases, deoxyribonucleases, intestinal nucleosidases, and phosphatases.

### Functions of Digestive System

The primary function of the digestive system is to transfer nutrients, water, and electrolytes from the digested food material into the body's internal environment (Jones et al. 2012). Along with the primary functions, it involves in three other functions:

**Avoiding autodigestion:** Digestive enzymes are used by the body for breakdown of complex molecules into smaller one. But at the same time, these digestive enzymes are not able to digest the GI tract cells. This pathological condition is known as peptic ulcers.

**Mass balance:** Another challenge to the digestive system is maintaining mass balance by matching the fluid input to the fluid output.

**Defense:** Another important function to the digestive system is to protect body from the foreign invaders which is entered via food.

### Crosstalk Between Endocrine and Digestive System

Endocrine system involved in the regulation of the various glands in the body and the secretion of hormones. One important function of the endocrine system is to control stomach acidic environment. Other functions are control of appetite, ease in the digestion of food, the regulation of energy balance, and the maintenance of blood glucose levels. These hormones are known as gastrointestinal hormones, which are secreted from enteroendocrine cells in the stomach, pancreas, and small intestine (Ziswiler and Farner 1972). Based on the structure, it is divided into three groups:

(a) Gastrin–cholecystokinin family: gastrin and cholecystokinin

(b) Secretin family: secretin, glucagon, vasoactive intestinal peptide, and gastric inhibitory peptide

(c) Somatostatin family

(d) Motilin family

(e) Substance P

**Gastrin family:** Gastrin family includes a family of homologous peptides, which are frog skin peptides (cionin), caerulein and phyllocaerulein, but cholecystokinin CCK and gastrin are the only known members of the family in mammals. Gastrin family is able to induce gastric secretion, stimulate pancreatic secretion, increase blood circulation and water secretion in the stomach and intestine, stimulate smooth muscle contraction, pancreatic enzyme secretion and growth, gallbladder contraction, intestinal motility, satiety, and inhibit gastric acid secretion. Apart from classical function, this family is also involved in the neurotransmission. From phylogeny, these peptides C-terminal domain is evolutionary conserved “Tyr-Met-X-Trp-Met-Asp-Phe-NH<sub>2</sub>” (where X in most mammalian species is a glycyl residue). One or two positions downstream, there is a conserved sulfated tyrosine residue (Lewis and Southern 2000).

**Secretin family:** It regulates the activity of G-protein coupled receptor, which includes secretin, calcitonin, glucagon, parathyroid hormone/parathyroid hormone-related peptides, and vasoactive intestinal peptide receptors. These peptides inhibits gastric gland secretion and gastric motility, increases the output of pancreatic juice rich in bicarbonate ions, stimulates insulin secretion, inhibits HCL production, increases bile output, stimulates buffer secretion, dilates intestinal capillaries, and relaxes intestinal smooth muscle.

**Somatostatin family:** It affects various parts of gastrointestinal tract (GI) such as stomach, small intestine, pancreas, gall bladder, and liver. Functionally, it inhibits gastric acid and pancreatic secretion, inhibits GI blood flow, and inhibits gallbladder contraction

and bile release. It is a regulatory peptide produced by neuroendocrine, inflammatory, and immune cells in response to ions, nutrients, neuropeptides, neurotransmitters, thyroid and steroid hormones, growth factors, and cytokines. It works when stomach gets emptied, then acidic environment need not to be maintained through negative feedback mechanism, and it inhibits the secretion of HCl.

**Motilin family:** Motilin family includes ghrelin and motilin peptide hormones that resemble 50% sequence similarity. Ghrelin is popularly known as “hunger hormone” and stimulates appetite, increases gastric emptying. Motilin works in a similar fashion, which works in a similar fashion as ghrelin.

**Substance P:** It is an undecapeptide neuropeptide which acts as vasodilator and regulates inflammation.

## Crosstalk Between Endocrine and Digestive System

Nervous system is also involved in the regulation of the internal organs and glands of the digestive system (Chapman 1985).

Functionally, it is divided into two parts:

### The sympathetic nervous system (SNS):

Its primary function is to stimulate “rest and digest” activities. SNS regulates vasoconstriction of blood vessels; inhibits gastrointestinal secretions, motility, and peristalsis; stimulates glycogen breakdown in the liver; and decreases pancreatic enzyme production and insulin release.

### The parasympathetic nervous system (PNS):

Its main function is to stimulate “fight and flight” activities. PNS performs reverse function as SNS.

**Digestive System, Table 1** Common disorders related to digestive system

| S.No. | Affected organs             | Disorders                                                             | Affected function                                                                                                     |
|-------|-----------------------------|-----------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------|
| a.    | <b>Tongue</b>               | <b>Ankyloglossia</b>                                                  | Tongue movement is restricted                                                                                         |
| b.    | <b>Salivary glands</b>      | <b>Mumps</b>                                                          | Inflammation in the parotid glands; disturbed chewing and swallowing of food                                          |
| c.    | <b>Esophagus</b>            | <b>Gastroesophageal reflux disease</b>                                | When acidity of the stomach juices, food, and fluids back up from the stomach into the esophagus                      |
| d.    | <b>Stomach</b>              | <b>Peptic ulcer</b>                                                   | Open sores present in the mucosal lining of the gastrointestinal tract and the upper portion of your small intestine. |
|       |                             | <b>Hiatal hernia</b>                                                  | Upper part of the stomach bulge through diaphragm                                                                     |
|       |                             | <b>Hypertrophic pyloric stenosis</b>                                  | Blocks food from entering the small intestine                                                                         |
|       |                             | <b>Vomiting</b>                                                       | Empty the stomach from mouth                                                                                          |
| e.    | <b>Intestinal disorders</b> | <b>Inflammatory bowel disease/ Crohn’s disease/ulcerative colitis</b> | Localized inflammatory degeneration                                                                                   |
|       |                             | <b>Irritable bowel syndrome</b>                                       | Abnormal intestinal mobility                                                                                          |
|       |                             | <b>Malabsorption syndrome</b>                                         | Abnormal nutrient absorption                                                                                          |
|       |                             | <b>Enteritis</b>                                                      | Any inflammation in intestine                                                                                         |
|       |                             | <b>Colon cancer</b>                                                   | Abnormal cell proliferation in colon                                                                                  |
|       |                             | <b>Constipation</b>                                                   | Slow movement of feces                                                                                                |

## Digestive System Disorders

Digestive system disorders are very common. Some are acute and some are chronic. These disorders many caused by eating bad quality of food followed by inflammation (Smith and Morton 2011). Some common digestive disorders are charted in Table 1 with respective affected organ.

## Definition

Diploid term defines two complete sets of chromosomes or copies of genome in a cell or an organism.

## Introduction

The organisms involved in sexual reproduction have two sets of chromosomes contributed by two sexually different parents *i.e.*, male and female parent. These two parents contribute haploid (n) set of chromosomes present in their gametes or sex cells to reproduce a diploid (2n) progeny (Fincham, 2001). Sexually reproducing plants and animals may have different diploid numbers. For instance, humans have 46 as diploid number (2n) and 23 as haploid number (n) of chromosomes. Similarly, the diploid number for chimpanzees is 48, for rhesus monkeys is 42, for zebra fish is 50, for Arabidopsis is 10, for peas is 14, for yeast is 32, for maize is 20, for mango is 40 and for rice is 24.

## Chromosomal Aberrations Due to Change in Ploidy Level

The number of chromosomes in a single basic set is called the monoploid (x) value. The chromosome number is termed as ploidy of organism and

**Diploid, Fig. 1** Flowchart showing aberrations in chromosome number due to variation in the ploidy level

the number of a complete set of chromosomes in an organism may increase or decrease. Changes in ploidy level can be categorized in two *i.e.*, euploidy and aneuploidy, which can be demonstrated by the flowchart given in Fig. 1. Euploidy involves variation in the complete set of chromosomes in a cell or an organism, which can lead to the increase in the copies of whole genome of that cell or organism for example,  $2n + n = 3n$ . However, aneuploidy occurs when there is an insertion or elimination of one or a few chromosomes for example,  $2n - 1$ : monosomic,  $2n - 2$ : nullisomic,  $2n - 1 - 1$ : double nullisomic,  $2n + 1$ : trisomic,  $2n + 2$ : tetrasomic,  $2n + 1 + 1$ : double trisomic (Griffiths et al., 1999).

Aneuploidy is caused due to segregational errors of chromosome participating in meiosis cell division. Aneuploidy in human may lead to changes in either autosomal or sex chromosomes resulting in fatal syndromes. Some examples of syndromes in humans caused by autosomal aneuploidy where the diploid number becomes 47 are Down syndrome (trisomy of 21st chromosome), Edward's syndrome (trisomy of 18th chromosome), Patau's syndrome (trisomy of 13th chromosome). Likewise, aneuploidy of sex chromosomes in humans may cause Turner syndrome (diploid number: 45, single copy of X-chromosome), Klinefelter syndrome (diploid number: 47, extra copy of X or Y- chromosome).

Euploidy is further classified into two cases: diploid and polyploid. As the name suggests, the diploid case is found in those organisms that

comprises two copies of the basic set of chromosomes. However, multiple copies of monoploid sets in an organism is identified as a condition called polyploidy. Polyploidy can be of two different types *i.e.*, autopolyploidy and allopolyploidy. Repetition of the same set of genomes in an organism causes autopolyploidy whereas multiplication of different sets of genomes in an organism results in allopolyploidy.

## Directed Versus Averted Gaze

Gabrielle L. Davidson  
Biological, Earth and Environmental Sciences,  
University College Cork, Cork, Ireland

### Definition

Directed and averted gaze refers to behavioral cues that provide information about where someone is looking. Gaze can be directed toward or averted away relative to someone or something. These gaze orientations can also refer to an individual's response to observing another's behavior. Gaze cues are used in social as well as anti-predation contexts.

### Introduction

Providing gaze cues and responding to gaze orientation are behaviors many of us engage in on a daily basis. We may have experienced being in a public area such as a train or bus and inadvertently looked toward a stranger, who, upon noticing that someone is looking at them, directs their gaze back. Immediately we tend to avert our own gaze so as to avoid any further eye contact with an unfamiliar person. In another scenario, we may have entered a busy room full of people and spotted a friend across the other side. We look directly toward them to catch their attention, causing them to look back, allowing us to greet one

another through mutual gaze. These two examples demonstrate how attention toward and sensitivity to gaze cues – either averted or directed – can be used to communicate information or to avoid confrontation. Gaze sensitivity typically presents in two forms: gaze following, whereby an individual tracks where the other is looking, and gaze aversion, whereby an individual avoids the gaze of another. Gaze following is especially prominent in social contexts in humans and many other animals. Gaze aversion is often found in predator-prey interactions, whereby prey avoids direct gaze, but also in social contexts such as the train scenario described above. Understanding the socio-ecological contexts in which humans and animals respond to gaze cues provides insight into how gaze sensitivity has evolved across species and the cognitive mechanisms that underpin it (Davidson et al. 2013).

### What Constitutes Directed and Averted Gaze?

Directed and averted gaze can refer to the cues that elicit gaze sensitivity responses and/or the responses themselves. For example, direct gaze (the cue) toward a stranger causes them to avert their gaze (the response). Gaze cues include the orientation of the head, the eyes, or both, and they may be in line with one another, or in opposing directions, such as the head directed straight but with eyes directed to the side. Gaze can be directed toward or averted away from someone or something.

### Why Are Individuals Sensitive to Gaze Cues?

Being sensitive to other's gaze can have many functional purposes. Gaze following can be used in several contexts including communication, competition, and avoiding predation. For example, looking someone directly in the eye and then averting gaze toward their shirt may communicate to the person that they have a button undone. Two builders working on a project may share mutual

gaze through direct eye contact, while they coordinate the movement of large equipment together. Animals living in social groups may benefit from attending to group members if they direct their gaze toward the sky, as this may be an indication of an aerial predator, or if a group member directs their gaze behind a bush, as this may be an indication that a food source has been discovered. Gaze aversion, by contrast, refers to avoidance behaviors in response to directed gaze. While most humans are comfortable sharing mutual gaze, people diagnosed with autism spectrum disorder typically avoid eye contact (Hadjikhani et al. 2017). In many primates, mutual eye gaze with another individual is considered a threatening display, causing subordinate individuals to avert their own gaze from dominant members to avoid aggression (Altmann 1967). Gaze aversion is also important for predator avoidance as forward-facing eyes and/or faces may represent a predator and therefore indicate whether it intends on initiating a pursuit. Fearful responses to eyes have been reported across a broad range of vertebrate taxa including fish, reptiles, birds, and mammals (Davidson et al. 2013).

### **Gaze Cues as a Paradigm for Testing Cognition**

In humans, eye gaze is at the heart of social cognition. Sharing gaze toward the same object (joint attention) or each other (mutual gaze) facilitates communication and demonstrates our capacity to recognize that others have mental representations of the external world because of what they can see and that these perspectives may be the same or different than our own. Through direct eye gaze, we recognize that we are sharing our attention toward each other and working toward the same goal, a cognitive mechanism known as joint intention (Tomasello and Carpenter 2005). These behaviors and underlying cognitive mechanisms are advantageous for communication within a cooperative society, and it is thought that the shape and appearance of the eye in humans are unique and have evolved to expose the white sclera around the iris, making eye

orientation conspicuous and easy to detect (Kobayashi and Kohshima 1997).

Gaze cues can be manipulated in experimental paradigms to test several questions related to gaze sensitivity including the features of the cues that elicit responses and the cognitive mechanisms that underpin these responses. Both human and nonhuman animals attend to gaze cues, but it is not always clear to what extent they share underlying cognitive mechanisms associated with behavioral responses to directed and averted gaze. For example, in the object-choice task, a human experimenter directs their gaze toward one of two cups to indicate the location of hidden food to the test subject (e.g., Anderson et al. 1995; von Bayern and Emery 2009). If the subject chose the correct cup more often than by chance, this demonstrates that they are following human-directed gaze to find food. In a test of gaze aversion, a human experimenter either looks toward or away from food, and a prey species, such as a bird, has to feed (e.g., von Bayern and Emery 2009). If the bird is more wary when the gaze is directed toward rather than averted away from the food, this is an indication that the subject is attending to and avoiding direct gaze. In the broadest sense, there are two interpretations with regards to cognitive abilities underlying gaze following and gaze aversion, which are often referred to as “low-level” and “high-level” interpretations. In the low-level model, animals respond to directed and averted gaze because they have learned that those cues are associated with predictable outcomes. In the high-level model, animals recognize that gaze cues indicate that another individual can see something, and some interpretations may go so far as to claim that this provides evidence that animals can reason about the minds of other social agents (i.e., theory of mind), albeit the latter is a rich and less accepted interpretation as animals may be responding to the cues, not to internal mind states.

### **What Gaze Cues Are Most Salient?**

Studies have shown that species vary in how sensitive they are to eye orientation compared to

head orientation (Tomasello et al. 2007; reviewed in Davidson et al. 2013) and that sensitivity to eye direction emerges after sensitivity to head direction in human infants (Corkum and Moore 1995). Some authors suggest that being more sensitive to eye direction as opposed to head direction may indicate an animal's ability to understand the relationship between eyes and mental representations of the world, but this interpretation is not robust because animals can still learn that eye direction is associated more predictably with certain outcomes than head direction. This is especially true when many experiments are performed on captive animals using human gaze cues, for example, to indicate the location of hidden food. Captive and hand-reared animals may have learned that human eyes always orient toward objects of interest. Moreover, because the visual systems of animals vary, including the positioning of the eyes on the head and the field of vision, directed or averted eye gaze may be irrelevant if eye movement within the optical orbit is restricted and gaze orientation occurs only through head movement (Davidson et al. 2013). Nevertheless, categorizing how animals respond to directed and averted gaze cues across a wide range of taxa enables us to understand the evolution and function of gaze sensitivity.

## Directional Selection

P. Dubey

Department of Zoology, Banaras Hindu University, Varanasi, India

## Synonyms

[Positive selection](#)

## Definition

Directional selection can be defined as selection of the organisms with traits underlying at the end of trait spectrum in nature.

## Introduction

Evolution takes place by many factors in any environment. Natural selection is one of the important evolutionary forces that act on organisms and create variation among them. Natural

selection is of three types: stabilizing selection, directional selection, and disruptive selection.

Directional selection is the most common form of natural selection observed in any trait during the course of evolution. It is a type of selection in nature that causes a population to evolve toward one end of a trait spectrum. Traits are found in two forms which are either discrete (e.g., eye color) or continuous (e.g., height); in discrete, only one form will be selected (e.g., black eye color), and in continuous, either the highest or lowest value for a trait is selected (e.g., tall people). Directional selection mostly occurs when a population migrates to new environment conditions, and the trait most favorable for their fitness is selected, and therefore this selection is often referred to as positive selection (Charlesworth and Charlesworth 2010). It mostly leads to selection for the extreme phenotype over the mean or another extreme.

Directional selection also occurs due to human activities. For example, bigger animals are being hunted either for meat or ornamentation, so small-sized animals are selected in nature. Similarly slow-moving animals are killed by their predators, which leads to the selection of mostly fast-moving animals in nature.

## Methods to Assess Directional Selection

There are different methods to assess directional selection like QTL sign test, Ka/Ks ratio test, and relative rate test. QTL sign test confirms whether any trait is due to directional selection or genetic drift (see ► [QTL Linkage Analysis](#)). It measures number of quantitative trait loci involved in the formation of a different phenotypic trait from one form to the other (Orr 1998). In Ka/Ks ratio test, Ka depicts nonsynonymous substitutions and Ks denotes synonymous substitutions. If this ratio is greater than 1, it depicts directional selection. In relative rate test, evolutionary rate between two closely related species are compared by taking a third one as a reference species.

The introduction of any allele in nature takes place by mutation. When an allele is introduced in a new environment, its frequency is very less, but

as the environment becomes favorable and the organism is adapted in the new condition, the frequency of that allele is increased (see ► [Gene Frequency](#)). Suppose there are two alleles for a trait, A1 and A2, which have frequency  $p$  and  $q$ , respectively, in nature, and both the alleles are found in three forms of genotype: A1A1, A1A2, and A2A2 with frequency  $p^2$ ,  $2pq$ , and  $q^2$ , respectively. For allele A1 to fix in the environment, the fitness of the organism being homozygous for A1 should be equal to or greater than any other genotype in the environment.

However the time taken by any allele to get fix depends on following factors:

If A1 is completely dominant over A2, then it will take many generations for A1 to get fixed, because the other allele A2 remains present in the heterozygous form without any effect on the fitness of the organism and therefore unexposed to natural selection, and by this, the recessive allele remains present in nature for long time period.

But if A1 is incompletely dominant over A2, then the heterozygotes have reduced fitness and they will not be able to survive leading to reduction in the frequency of A2. So A1 will be fixed in nature in less number of generations (Futuyma 1998).

There are many examples of directional selection found in nature.

Haldane (1924) estimated the strength of selection of a trait by observing the change in allelic frequency in the two forms of *Biston betularia* (peppered moth). In Northern Europe, before the advent of the Industrial Revolution, the density of light form of peppered moths was far more than the dark-colored form of the moths. But as the number of industries increased in number and pollution increased the concentration of carbon in the environment, it caused blackening of tree barks; the light form of moths was not able to adapt accordingly and decreased in number, and this form was replaced by the dark form of *Biston betularia*. It occurred because the light form was not able to hide themselves against the dark-colored barks and was killed by their predators. The black form was thus selected in the new environment.

DDT resistance reported in mosquitoes is one of the examples. This insecticide was introduced

to kill mosquitoes which are responsible for malaria. When DDT was used for first few times, it was found to be very effective as it declined the mosquitoes' population rapidly, but after many continuous uses, the small number of resistant mosquitoes multiplied, and no further effect of DDT could be observed after any further application. This indicates the selection of the resistant mosquitoes against the application of DDT. Another example of drug resistance had been reported in HIV-1 virus where it was found that the virus acquired drug resistance mutations (DRAM) with the application of antiviral drugs (Murrell et al. 2012).

Directional selection was reported to shape the oral jaw apparatus in Lake Malawi cichlid fishes. Cichlid fishes have three general modes of feeding, and depending on the mode of feeding, they have different head shapes (Liem 1991). Further specialization of jaws and teeth depends on the specific foraging niches (e.g., biting fins or biting algae) (Kocher et al. 1993). It was analyzed that diversion in the shape of jaw in these fishes is due to directional selection and not genetic drift and that analysis was done through QTL test (Albertson et al. 2003).

## Kin Selection

The concept of kin selection is an important part underlying directional selection. It is mostly observed in many eusocial insects like that of Hymenoptera (honeybees, wasps, and ants) and termites and in a few mammals such as the naked mole rat (Frank 1998). Eusociality means an organism gives up its fitness in order to increase the fitness of its relatives. This behavior is called altruistic behavior. Hamilton (1964) gave a rule that explains the survival and selection of these altruistic organisms which exhibit this extreme level of "selflessness." The rule is as follows:

$$C < r \times B$$

According to this rule, the cost ( $C$ ) incurred by giving up self-fitness by altruistic individual should be less than the product of genetic

relatedness ( $r$ ) of the altruistic organism with its relative and the benefit ( $B$ ) obtained by the individual for whom altruism had been done.

In kin selection, allelic variant that causes its carriers to lose its fitness has the advantage to increase the fitness of related individuals, and this variant thus increases among organisms. Suppose the altruistic behavior is controlled by a gene and it is randomly distributed in a group of genetically related individuals. In this group few may be donors in altruism and others are recipients. Whenever donor sacrifices its fitness, the gene for altruism is lost with it but increases with high frequency in the recipient organisms. Genetic relatedness is not the only responsible factor for the selection of this trait; interactions between the donor and recipient are also necessary for both to memorize the past behavior of the other and to punish those who had cheated (Charlesworth and Charlesworth 2010).

## Discrete Trials

Meredith S. Berry

Sciences, Behavioral Pharmacology Research  
Unit, Johns Hopkins University School of  
Medicine, Baltimore, MD, USA

## Introduction

Discrete trials (DT) procedures are frequently used to study nonhuman animal behavior and

cognition in a laboratory setting. For example, discrete trials can be used to examine behavioral and cognitive processes such as drug self-administration (e.g., Stretch and Gerber 1977), memory (e.g., delayed matching to sample tasks; Berry and Odum 2014), delay discounting (thought to measure impulsive decision-making, e.g., Woolverton et al. 2007), and stimulus control (Hinson and Higa 1989). Many schedules of reinforcement exist that define the presentation of a reinforcer following a given behavior (e.g., lever pressing or key pecking), from simple fixed ratio schedules to complex concurrent or chain schedules. Discrete trial procedures allow the experimenter to precisely control the timing of trials and earned reinforcers across a session following a given behavior (Dobrin and Roberts 2012). While discrete trial paradigms can be used to understand behavior and cognition among human subjects, the focus of this piece will be on the use of discrete trials in nonhuman animal research.

## On the Mechanics of Discrete Trials

Discrete trials procedures involve dividing a session into multiple trials so that there are individual distinct trials and intertrial intervals (ITI; the time period immediately following a discrete trial in which reinforcers are not available) (Dobrin and Roberts 2012). Specifically, each trial begins at a fixed point in time within a session, lasts for a prespecified period of time, and is then followed by a predefined ITI time period. For example, a session may begin at 8:00 a.m. and end at 9:00 a.m., with three discrete trials within the session. A trial may last for 15 min, with a 5-min ITI following the trial. When described in terms of discrete trials per hour, this is referred to as a DT3. Each discrete trial might be associated with exteroceptive stimuli signaling the beginning of the trial (e.g., house light, key light, light above a lever). During the ITI, these stimuli may change or extinguish to signal the end of that trial and the onset of the ITI.

In intravenous self-administration research, controlling the timing of drug delivery is crucial,

as free access to drug over long periods (e.g., 23-h sessions over several weeks) can result in toxicity and can be lethal (Johanson et al. 1976). To provide a specific example from a discrete trial drug self-administration paradigm, a dose of 1.0 mg/kg of cocaine per infusion might be delivered to a rat over the course of three discrete trials per hour (DT3). The infusion might be earned on a fixed ratio 1 (FR 1) schedule of reinforcement, in which a single lever press results in an infusion (see Roberts et al. (2002), for an example of several discrete trial self-administration preparations).

Discrete trials are also commonly used to examine memory processes. One example is a delayed matching to sample (DMTS) task (Blough 1959). In this task, a sample stimulus is presented (e.g., a blue key light), and then removed for some amount of time (e.g., 30 s). Then the same stimulus, along with a “distractor” stimulus (referred to together as comparison stimuli) is presented again. The organism chooses one of the two comparison stimuli presented. If the choice matches some physical property (e.g., color) of the previously presented sample stimulus, then the response is correct, and a reinforcer (e.g., food) is provided. Thus the organism is required to remember the first stimulus to accurately respond and receive reinforcement. Accuracy of remembering tends to decrease with increased time between the sample and choice stimuli. Following the DMTS trial, an ITI is presented as in other discrete trials procedures to standardize the overall timing of each trial across the session.

The types of discrete trials outlined above (i.e., discrete trials used in self-administration research or memory research) allow for assessment of behavior when exposed to discrete trials compared to other procedures, or the effects of various independent variables that might be of interest to the experimenter. For example, an experimenter might be interested in differences between patterns of drug self-administration in discrete trial paradigms compared to free access to the drug. Or a researcher may be interested in drugs or manipulations that enhance memory performance.

## Discrete Trials Data Analysis

Data from discrete trials procedures can be analyzed and displayed in numerous ways. The behavior of interest – such as how much drug is self-administered, or memory performance – can be aggregated within a session and compared across sessions to examine how behavior changes over time. For instance, one way to analyze discrete trial data would be to examine percentages over time (e.g., percentage of the available infusions taken over time, percentage correct of memory performance over time). A researcher could also analyze percentages before or after a manipulation or introduction of an independent variable.

## Conclusion

Discrete trials (DT) procedures are frequently used to study a wide range of nonhuman animal behavior and cognition under controlled laboratory conditions. Discrete trial procedures offer a way to control the precise timing of events within a session (e.g., reinforcer delivery, onset timing of each trial).

## Discrimination of Emotion

Jennifer Vonk  
Department of Psychology, Oakland University,  
Rochester, MI, USA

## Synonyms

[Cognitive empathy](#); [Emotion detection](#); [Emotion recognition](#)

## Definition

Emotion discrimination is the ability to perceive differences between the emotions of others as expressed in facial expressions, body postures, sounds, chemical signals, and other observable cues. The ability to discriminate between emotions implies only that an organism recognizes differences between these physical cues and can potentially predict different behavioral outcomes on the basis of these cues (Waller et al. 2016). However, the capacity to discriminate between the unique external cues of different emotions is not equivalent to the capacity to represent the internal emotion states of others – an ability sometimes labelled as “cognitive empathy” (see Nieuwburg et al. 2021).

## Adaptive Value

It is adaptive for many organisms to attend to the signals of emotion in others. Arguably, fear, anger, and disgust are the most important emotion cues to recognize because they signal potential threats to the organism. For example, recognizing signatures of fear in others can encourage an organism to take cover or retreat from a potential threat. Recognizing the cues of anger can encourage an organism to deescalate a potential rise in conflict that could result in physical aggression. Recognizing that another individual is likely to aggress can encourage self-protective behaviors against potential harm. Recognizing the cues of disgust might discourage an organism from entering an area or interacting with an object that contains pathogens or from consuming a spoiled or toxic substance. Although it may be most useful to read emotion cues in conspecifics, this is a skill that has utility beyond the social group. For example, sympatric species can recognize and respond to alarm calls in members of other species (Carlson et al. 2020; Palmer and Gross 2018), and even solitary animals may leave an area where scents or released chemicals signaling fear/danger have been left behind by other organisms (McKillup and McKillup 1995). Therefore, despite the focus on studying emotion

discrimination in social species, it is important that the study of this topic is extended to less social animals as well.

It is unclear the extent to which animals might recognize other basic emotions like happiness, sadness, and surprise. Several species recognize and respond appropriately to signals of play, for example, dogs, primates, and bears (Taylor et al. 2019). Play faces or postures can signal to a conspecific that the intent of an individual is to play rather than to harm, even though the ensuing behavior may mimic an aggressive behavior. Recognition of happiness and sadness may be important to humans and other altricial social species to encourage bonding because infants depend upon extensive care from adults (Palagi et al. 2019). Smiling emerges early in human infants and is postulated to increase bonding. Crying, on the other hand, signals some essential need that is currently unfulfilled and may be crucial in allowing the altricial infant's needs to be met. Later in life, recognizing when another is sad allows for the provision of comfort and may be important for empathy. Although controversial, some have argued that other species, in addition to humans, are capable of affective empathy, which involves the internalization of emotions detected in others or feeling what another is feeling (de Waal 2004).

The secondary emotions, such as guilt, shame, embarrassment, pride, and jealousy, are more difficult for even humans to discriminate in the facial expressions of other humans compared to the basic emotions (Ekman 1993). Recognition of these emotions plays an important role in moderating social interactions but may be less directly critical for survival. Therefore, we might expect recognition of these emotions to be restricted to species that form long-term bonds, but this is not necessarily restricted to large social groups. Recognition of these emotions may be important for animals that pair-bond or whose offspring have long periods of dependency. However, there is little research indicating whether other species recognize the expression of these emotions, and in fact, it is controversial whether other species even experience secondary emotions.

## Modalities

It is also important to recognize that although researchers have tended to focus on the recognition of facial expressions, probably because facial expressions are one of the most important ways in which humans convey emotion, animals use a much richer range of sensory modalities to detect cues of emotion. For example, sounds, chemical signals, postures, and tactile cues may signal another individual's emotion state. For some animals, aggression or affiliation can be predicted from the position of the ears; the movement of the tail; the overall posture; hissing, growling, or snarling sounds; and piloerection. It is likely that animals convey emotion in other ways not recognized by humans. This entry will focus on the recognition of emotion in visual displays, especially facial expressions, because this is the modality that has undergone the most experimental study (see also Nieuwburg et al. 2021). In addition, almost all of the experimental work has been conducted with nonhuman primates, with some work on domestic species and their understanding of human emotion. There is less research focused on how animals understand the emotions of their conspecifics and virtually no work in non-mammals or less social species.

## Experimental Tests of Emotion Discrimination

Human faces can convey a range of emotions due to the flexibility of movement of facial muscles. Even in other apes, the movement of the facial muscles is more restricted, limiting the range of expressions that can be conveyed solely through facial movements. However, there are enough similarities that allow humans to recognize characteristics such as the sneer as conveying threat and the relaxed mouth as conveying playfulness or friendliness (Waller and Micheletta 2013). It has been suggested that domestic dogs have evolved the ability to communicate with humans by adopting expressions that humans recognize. For example, eyebrow movements convey fear and sadness, which evoke sympathy and

compassion from humans (Kaminski et al. 2019). Humans can also categorize expressions of emotion in cats, such as frustration, fear, and relaxation. Interestingly, cats seem to intensify these expressions when interacting with humans, suggesting that these emotion expressions have also been influenced by the process of domestication (Bennet et al. 2017).

### Hidden Object Paradigm

The hidden object task has been a popular paradigm for testing the discrimination of emotions in animals. In this paradigm, humans direct their attention while expressing different emotions to different objects, such as closed containers. Studies have been conducted with happy, neutral, fearful, and disgust expressions directed toward boxes. Both domestic dogs and chimpanzees chose to receive the contents of a box to which humans had directed positive emotions rather than disgust expressions, but they did not discriminate between positive and neutral emotions in this context (Buttelmann et al. 2009; Buttelmann and Tomasello 2013). Unlike the dogs and chimpanzees tested in the object choice task with human experimenters, capuchins did not discriminate based on human experimenters' cues. However, they were able to make use of the emotional responses of conspecifics to preferentially open boxes to which groupmates had directed positive expressions (Morimoto and Fujita 2012).

Merola et al. (2014) tested domestic dogs in a similar task and found that dogs preferred to investigate a box that caregivers had directed happy emotions toward in comparison to neutral or fearful emotions. However, they did not show preferences between boxes that caregivers had directed fearful versus neutral expressions. These researchers speculated that dogs had learned to attend to owner's positive expressions because they were often associated with reward. This interpretation emphasizes that it is not necessary to postulate underlying mental representation of others' emotions on the basis of successful discrimination of emotion expressions.

### Social Referencing

In a different paradigm, the same research team investigated whether domestic dogs and cats

could read the cues of human caregivers to signal whether a novel object was safe or dangerous. They found that both dogs and cats engage in social referencing, meaning that they gaze back to their caregivers and study their emotional and postural cues before deciding whether to interact with an ambiguous novel object or situation. Both dogs and cats behaved differently depending on whether their owners displayed positive or negative expressions and vocal cues (Merola et al. 2015). However, only dogs mirrored their caregivers' responses to these objects, again leading the investigators to postulate that they were engaged in observational conditioning (Merola et al. 2012). Similarly, Yong and Ruffman (2015) found that dogs were more attentive to caregivers that displayed fearful or confused expressions compared to those that displayed happy expressions, but they interpreted these findings as suggesting that dogs seek more information in ambiguous situations, not that the dogs necessarily understood their caregivers' emotional states. Cats also looked more to their caregiver than an unfamiliar human when the two humans engaged in antagonistic conversations. They showed a similar but nonsignificant preference to look at their caregiver during friendly conversations between the same humans as well (Galvan and Vonk 2016). The stronger effect of social referencing for negative conversations supports the conclusions of Yong and Ruffman (2015) that such differences reflect learning rather than understanding of the meaning of emotions.

### Matching Experiments

In one of the earliest studies to explore nonhuman primates' representation of emotion, Dittrich (1990) successfully trained long-tailed macaques to select a target facial expression from three line drawings of different emotional expressions. In another groundbreaking study, chimpanzees successfully matched images of chimpanzees conveying positive or negative emotions to videos of negative or positive scenarios such as veterinary needles or favored rewards (Parr 2001). Although the chimpanzee's performance was impressive, it might reflect associations between facial expressions witnessed during experienced

events similar to those depicted in the test stimuli. That is, the chimpanzees did not need to represent the scenarios as evoking a particular underlying emotion in order to associate the correct emotional expression with the matching scenario. It may not be possible to tease apart mechanisms that involve representations of emotions as mental states from mechanisms that involve representations of the observable manifestations of those emotions because the former depend upon the latter and cannot be separated in experimental tests with nonverbal organisms. Nonetheless, the matching-to-sample paradigm has been useful for demonstrating which other primate species can differentiate emotional expressions and which emotions can most readily be differentiated (reviewed in Nieuwburg et al. 2021).

Cross modal matching tasks have also been used to demonstrate that animals associate verbal cues linked to certain emotions with their corresponding facial expressions – at least hinting at a unified representation of individuals experiencing particular emotions. In these tasks, animals are not required to explicitly select a stimulus that matches the sample as in Parr's (2001) study. Instead, researchers make use of looking time to determine whether animals look longer when the vocal cue is a match compared to when it is a mismatch with the visual stimulus presented. For example, dogs looked longer at images of happy or angry dog faces that matched positive or negative auditory stimuli of dog vocalizations and showed a similar pattern with human voices and vocalizations (Albuquerque et al. 2016). Similarly, Quaranta et al. (2020) found that cats looked longer when cat and human vocalizations matched the valence of facial expressions presented simultaneously compared to when they mismatched. However, the cats did not show this pattern when presented with cats expressing positive emotions. Thus, the results, at least for the cat stimuli, indicated that the cats were particularly attentive to whatever image was shown when the auditory sample of cats hissing was presented. The study also involved a small sample (ten cats) and presented very few stimuli (one trial with each human and cat stimulus for a total of four stimuli), so it is difficult to know whether the results would generalize.

Interestingly, in both of these studies, subjects looked longer at congruent stimuli (where the vocalization matched the valence of the visual stimulus). However, this contrasts with the typical interpretation of data from the well-established violation of expectation paradigm where subjects are expected to look longer at surprising stimuli. In this case, one would consider the results indicative of understanding emotion if animals looked longer at incongruent rather than congruent stimuli. Indeed, horses showed exactly that pattern in two similar studies, looking longer during the incongruent trials (Nakamura et al. 2018; Trösch et al. 2019). Thus, opposing patterns of results were interpreted as reflecting the same underlying ability, which is problematic.

Similar to studies with cats (Galvan and Vonk 2016) and dogs (Merola et al. 2015) that showed greater attention and differentiation when responding to their caregivers, the horses in Nakamura et al.'s study showed this typical effect only when presented with the voices of their familiar caretakers, but not with strangers' voices. Horses also reacted more negatively when angry human vocalizations were presented compared to joyful vocalizations (Trösch et al. 2019). Furthermore, Yong and Ruffman (2016) found a null result where dogs did not look differently at congruent versus incongruent stimuli in a similar task. However, these authors did find that dogs showed a general preference to view angry or happy human faces compared to sad faces, which does suggest that they differentiated between emotions. Other studies, in contrast, failed to show differences in dogs' viewing time as a function of human emotion expression (Correia-Caeiro et al. 2020). The fact that dogs' visual scanning was more rigid than in humans and that not all companion dogs and cats are sensitive to caregivers' or unfamiliar humans' expressions suggests that their processing of emotional information differs from that of humans.

### Neural Correlates of Discrimination

In addition to examining looking time and scanning patterns, researchers have examined physiological outcomes, such as heart rate and functional asymmetries in the processing of emotional stimuli. For example, left-gaze biases are a recognized

lateralized response to negative stimuli. Dogs showed a bias to turn their heads to the left (implicating the right hemisphere) when shown human faces expressing anger, fear, and happiness, whereas they showed a bias to turn their heads to the right if the human faces expressed surprise (Siniscalchi et al. 2018). Horses show the same left-gaze bias to negative stimuli of angry human faces, along with an increase in heart rate (Smith et al. 2016). Horses also show a left-hemisphere (right ear) bias when listening to positive human vocalizations (laughter) extending the findings to auditory stimuli (Smith et al. 2018). However, when Smith et al.'s (2016) data was reanalyzed using more sensitive measures (heart-rate changes between baseline and test, maximum heart rate, or recovery time), the evidence that horses differentiated between emotions disappeared (Schmoll 2016). Although these results do not demonstrate that animals differentiate between different emotions, they do indicate a general sensitivity to human facial expressions and vocalizations in both dogs and horses. Thus, this is a promising area of further research.

### Behavioral Differentiation

Studies of behavior have also supported the idea that various domestic species can differentiate human emotions. For example, cats engaged in more positive behaviors and spent more time with their primary caregiver when the caregiver expressed happiness compared to anger (Galvan and Vonk 2016). However, the same cats did not differentiate between an unfamiliar human expressing the same emotions, suggesting a role of learning to associate owners' positive expressions with positive outcomes as was suggested for dogs by Merola et al. (2012) and Yong and Ruffman (2015). Cats do not seem to learn to associate characteristics to humans through watching third-party interactions, even those involving different emotional responses (Leete et al. 2020). Horses, on the other hand, respond differently to humans that laugh versus growl and behave with increased freezing and vigilance to negative emotional vocalizations of humans (Smith et al. 2018). Horses also respond differently to videos of positive and negative interactions

between humans and other horses and even choose to touch the negative experimenter significantly more than the positive experimenter. Although the direction of this effect is counterintuitive, the fact that horses differentiated in their responses supports the conclusion that they discriminated the negative and positive contexts of the interactions. The authors suggested that the preference to touch the negative experimenter may reflect attempts at appeasement (Trösch et al. 2020). Proops et al. (2018) additionally demonstrated that horses could remember the emotions expressed in photographs of unfamiliar humans and behaved in a manner that matched the valence of the individuals' faces in the previously presented photographs when they later met those individuals. The sensitivity of horses to human emotions may reflect a more selective domestication process by humans and a stronger selection pressure for group-living in horses compared to solitary and self-domesticated cats. Of course, highly social species, such as crows, that do not have close relationships with humans might not be expected to differentiate human emotions (Clucas et al. 2013), but it will be important to learn what they understand of each other's emotions in future studies.

### Conclusions

Thus far, it appears that domestic species and non-human primates are capable of differentiating between emotional expressions in both their conspecifics and in humans. Although it appears that social species may be more adept at discriminating emotion compared to nonsocial species like cats, many more species need to be tested. It is important to keep in mind that facial expressions, and other cues of emotion, have likely evolved to be species specific, and thus, failure to recognize emotions in other species, including humans, should not be taken as evidence that animals cannot recognize and discriminate emotions in members of their own species. Much more data is needed using naturalistic paradigms in which animals with appropriate early socialization to members of their own species use expressions of emotion to adjust their behavior appropriately. Studying

emotion discrimination in a more diverse group of animals will contribute to a better understanding of the evolution of these abilities. Several recommendations for future research directions are described in Nieuwburg et al. (2021).

## Discriminative Parental Solicitude

Randy Corpuz  
Department of Psychology,  
Boston, MA, USA

## Synonyms

Interbrood conflict; Intra brood conflict; Mother-fetus conflict; Parent-offspring conflict

## Definition

Parents are expected to differ in the amount of investment allocated to offspring as a function of a multitude of factors including resource availability and offspring health.

## Introduction

Across species, conflict between parent and offspring is routine. The notion that parent and offspring – as a result of the former relying on the latter to achieve reproductive success – should exist in harmony may be intuitive. However, not all offspring are created equal; each individual offspring can vary in its reproductive value (e.g., health, probability to reach reproductive age). Each situation for parents can also vary from one context to the next (e.g., resource availability). This review will start with the logic of parent-offspring conflict theory. The focus will then shift to a very brief summary of the empirical work on discriminative parental solicitude (where the preponderance of work is specific to avian species).

## Parent-Offspring Conflict Theory

Trivers' (1974) original formulation of parent-offspring conflict theory (POCT) is based on Hamilton's rule, the fundamental formulation of kin selection theory (Hamilton 1964):

$$rB > C$$

In this formulation, the relatedness coefficient ( $r$ ) can range from 0 to 1. This coefficient, a representation of the probability that any two individuals share the same allele at any given locus, is critically important to understanding discriminative parental solicitude. The relatedness between a parent and offspring is  $r = 0.5$ : An individual allele present in a parent has a 50% probability of ending up in any of their given offspring. Parents and their offspring are expected to share the same alleles (across *all* loci) 50% of the time. Critically, while a parent shares 100% of its alleles with itself ( $r = 1.0$ ), an individual parent only shares 50% of its alleles with a given offspring. The optimal level of investment from the parent's perspective differs from the optimal level of investment from the perspective of the offspring.

There is a conflict of interest between parent and offspring. Parent-offspring conflict theory proposes that a battle over resources between offspring and its parent is ongoing. Parents (often mothers) seek to preserve resources for their own survival as well as retaining sufficient resources to invest in additional offspring (current or future).

### Intrabrood and Interbrood Conflict

Among some birds, multiple offspring can be produced simultaneously. This leads to intrabrood conflict. Each offspring in a given clutch can benefit from attempts at eliciting a disproportionate amount of resources toward itself at a cost to its siblings. Mothers, equally related to each bird, might be expected to resist such bids and be motivated to invest in each offspring equally. However, if mothers can distinguish which offspring have relatively greater odds of surviving (and thus reproducing), the return on investment for each unit of investment can be maximized. From this perspective, some offspring will receive a greater share of investment than its siblings.

In those species that raise multiple dependent children of *different* ages, each offspring competes for investment with current and with future offspring. This *interbrood* conflict leads to the

prediction that offspring will be selected to force parents to supply resources that the parent would prefer to withhold for future reproduction. Parents should be equipped with mechanisms that can facilitate discriminative solicitude (for an example in humans, see Daly and Wilson 1988) to allow parents to make “informed bets” on a given offspring by sampling a variety of informational cues (e.g., reliable cues that can indicate availability of resources and/or reproductive value).

Offspring in utero do not directly compete with existing siblings for energetic resources. However, energy invested toward fetal development does so at a cost to existing offspring. Parents tend to invest slightly more than optimal but still less than what would optimal for a given offspring.

### Examples

A range of factors influence the cost-benefit calculation of investing (or not) in a given offspring. These include (among others) resource availability and offspring reproductive value.

### Offspring Reproductive Value

Parental investment will be more effective when restricted to offspring likely to survive. Parents must discriminate among offspring according to the expected reproductive success of that individual. Informative cues reliably associated with the probability of surviving can be markers of the offspring's quality like size, health, and competitive ability. Resources are finite. The ability to gauge the probability of an offspring's reproductive prospects would be adaptive. Offspring that are unhealthy or unlikely to reproduce would have been unwise investments for any parent. Across species, infants who show cues to low quality (e.g., small birthweight, physical deformity) would have been unlikely to survive (much less reproduce). Mothers with low resources are particularly at increased risk to abuse or neglect their low reproductive value offspring (Daly and Wilson 1988).

### Environmental Condition

In environments where resources are scarce, parents have to be increasingly cautious in their resource allocation decisions. In birds, scarce energetic resources lead to mothers biasing their (caloric) investment toward larger, more competitive offspring. At times, this comes at a cost to their smaller offspring who will sometimes starve as a result (Gottlander 1987; see Royle and Rubenstein 2004 for a comprehensive review).

### Reproductive Value and Environmental Condition

Investing in offspring has diminishing returns. Investment beyond a certain level will begin to yield reduced returns per unit of investment. A mother has two options when confronted with a low reproductive value child: (1) decrease investment – a strategy that is lower in risk (lower cost) and increases a mother's ability to divert resources to “safe bet” offspring at a direct cost to low reproductive value offspring fitness; (2) increase investment – a risky strategy but, if able to meet the offspring's amplified needs, parents may pay these high costs in exchange for the promise of increasing their own reproductive success.

This contingent model of parental investment predicts that mothers utilize cues of resource availability *and* child reproductive value to calibrate an investment strategy that maximizes a parents' reproductive success. When resources are scarce, mothers serve their reproductive interests best by investing in healthy offspring (see above). However, when resources are more plentiful, the contingent model *uniquely* predicts that mothers will invest disproportionately in high-risk offspring since resources are ample to allow all children to survive. Even in times of abundance, mothers face tradeoffs. At excessively high levels of parental investment, recipient offspring may be unable to take advantage of investment over and above a threshold. When mothers have ample resources, investment in high-risk offspring (as opposed to the diminished returns from concentrating investment exclusively in high value offspring) is part of a diversified investment

strategy that can pay dividends in terms of reproductive success for a mother.

Empirical support for this “if:then” pattern comes from a range of sources. Davis and Todd (1999) conducted a computer simulation study in which they made a test of the reproductive benefits offered by different parental investment strategies with different offspring (among birds). A simple heuristic emerged: When resources were scarce, the most successful strategy was to feed the chick with the greatest reproductive potential first. However, when resources were more plentiful, the most successful strategy was to feed the smallest chick first. Support for this pattern of investment comes also from evidence obtained regarding parental investment strategies from observations of some birds (Gottlander 1987) and some nonhuman primates (Nakamichi et al. 1996). It is important to recognize that parents show (automatic) decision processes that reflect the relative costs and benefits of their offspring as well as the accessibility of resources in their local environment.

### Weaning Conflict

One arena (out of many) for conflict that appears across mammals is that of weaning conflict – an example of discriminative parental solicitude that operates concurrently with parental cognitive machinery. The duration of breastfeeding and the specific timing of weaning have significant relevance to the developmental outcomes of children. In primates, weaning processes coincide with the resumption of mating (Maestripieri 2002). The amount of weaning conflict is expected to increase around the time when mothers begin to reallocate investment toward producing new offspring. Some primate infants increase nipple solicitation when mothers resume fertile ovulatory cycles, a solicitation that mothers must resist. Spotted hyena mothers wean offspring at approximately 12 months of age when resources are available but often delay weaning until 18 months of age when resources are scarce or predators are present (Hofer and East 1995). Weaning conflict is a good example of mothers monitoring and strategically responding to the reproductive value of

their current offspring and current environmental conditions.

## Conclusion

Discriminative parental solicitude is expected to be ubiquitous across species. Much of the evidence for this expectation comes from research on birds and some research on humans. In understanding the logic of discriminative parental solicitude, one can begin to understand the predictors of such behaviors that, on the surface, seem maladaptive such as infanticide – a strategy that appears across a range of species including humans (see Daly and Wilson 1988). The application of discriminative parental solicitude to understanding the adaptive functions of specific decisions made by parents will continue to be a fruitful area of research for generations to come. As research progresses on fields of study such as genomic imprinting, prenatal development, and epigenetics, there exists the potential for burgeoning empirical work that integrates models uncovered through the predictive nature of discriminative parental solicitude.

<sup>2</sup>School of Psychology, Cardiff University, Cardiff, UK

“The term ‘disgust’, in its simplest sense, means something offensive to the taste. It is curious how readily this feeling is excited by anything unusual in the appearance, odour or nature of our food”. Charles Darwin: *The Expression of the Emotions in Man and Animals*, 1872 (p. 256)

## Introduction

Do animals have emotions, as people have emotions? Current research in comparative psychology and affective neuroscience certainly suggests

that at least some nonhuman animals experience a range of basic emotions, including anger, fear, disgust, happiness, and sadness (Panksepp and Biven 2012). Emotions in animals were first described by Charles Darwin in his book of 1872 entitled *The Expression of the Emotions in Man and Animals*. In line with his evolutionary theory on the origin of species, Darwin argued that there was no fundamental or qualitative difference between people and animals in their affective responses to emotional events, suggesting that emotions are adaptive and serve communicative and motivational functions. This entry concerns the emotion of disgust in animals. It focuses on the behavioral (facial) expressions accompanying this fundamental emotion, the measurement of hedonic impacts of taste stimuli, as well as the brain systems that mediate the learning and expression of disgust reactions. Finally, the contribution of animal models of disgust for therapeutic treatments for nausea in humans is examined. Disgust can be defined as a marked aversion toward something distasteful, an adaptive reaction to potentially harmful foods accompanied by physiological and behavioral changes in the organism. As described by Darwin, “extreme disgust is expressed by movements round the mouth identical with those preparatory to the act of vomiting” (Darwin 1872, p. 257). Formal investigations have confirmed Darwin’s observation and demonstrate that orofacial reactions provide a key way to measure disgust in nonhuman animals.

### Affective Expression of Disgust

In natural environments, food poisoning is a substantial threat. Many species (including humans) readily learn to avoid foods or fluids paired with toxins that have previously caused them gastrointestinal malaise by acting on the emetic system of the midbrain and brainstem. This phenomenon is termed conditioned taste aversion and potentially represents a key behavioral mechanism for toxin avoidance as well as providing a useful model for the study of disgust in humans (Reilly and Schachtman 2009). According to Garcia’s

seminal demonstration of taste aversion learning in rats (Garcia et al. 1955), pairing a novel taste with nausea (e.g., produced by the administration of emetic drugs as lithium chloride) not only results in a reduction in consumption of that taste but also produces a reduction in its hedonic value or palatability that can be revealed by means of different techniques which allow the assessment of the animal’s affective reactions to taste stimuli. One of these techniques is the taste reactivity test (Grill and Norgren 1978) which is selective to disgust, in contrast to decreases in the voluntary intake of the taste which may simply reflect taste avoidance without a change in hedonic responses. In this test, rats are infused with a flavored solution via a cannula implanted in their oral cavity, and the orofacial reactions – stereotyped oral motor and somatic consummatory responses – elicited by the flavor are analyzed. These responses can be classified as aversive (i.e., disgust responses) such as gaping, chin rubbing, and paw treading (elicited, e.g., by unpleasant sour or bitter tastes) or appetitive reactions such as tongue protrusions and paw licks (elicited, e.g., by pleasant sweet tastes). It is important to note that some components of these patterns of taste reactivity are universal across many species including human infants, primates, and the rat (Berridge 2000). Figure 1 shows the most characteristic components of the orofacial reactions to sweet tastes (tongue protrusion) and bitter tastes (gaping response) in different species.

When infused with a palatable taste previously paired with lithium-induced nausea, rats display aversive orofacial reactions reflecting a shift in the hedonic value, or palatability, of the flavor from positive (appetitive) to negative (aversive). The taste reactivity test has revealed that rats display disgust reactions – being gaping the most sensitive and predominant aversive reaction – to flavors paired with drugs as lithium chloride, cyclophosphamide, or apomorphine that produce vomiting in species that are capable of vomiting (Parker 1998). Furthermore, pharmacological treatments with drugs that alleviate nausea (serotonin antagonist, cannabinoid agents) interfere with the establishment of disgust reactions to a nausea-paired flavor without affecting the

**Disgust, Fig. 1** Examples of affective responses to taste stimuli by human infants, primates, and rats (*top*, tongue protrusion (appetitive); *bottom*, gape (aversive)) (Based on Berridge and Kringelbach 2015)

amount consumed of the flavor (Limebeer and Parker 2000; Parker et al. 2011). Moreover, rendering a flavor familiar through simple exposure prior to aversion conditioning attenuates the acquisition of disgust reactions if that flavor is subsequently paired with nausea (López et al. 2010). Therefore, a reduction in taste palatability, as reflected by disgust reactions in the taste reactivity test, appears to be correlated with the acquisition of a nausea-induced taste aversion (Parker 2014).

Critically, not all types of aversive events have the same effects. Pairing a flavor with pain produced by either footshock (Pelchat et al. 1983) or the injection of hypertonic saline (Dwyer et al. 2017) results in a reduction in subsequent voluntary reduction of that flavor, but no increase in aversive taste reactivity responses indicative of disgust. Further evidence that taste aversion is mediated by internal nausea linked to disgust reactions includes the fact that rats can suppress the intake of flavors paired with rewarding drugs, such as cocaine or amphetamine, that do not result

in the production of orofacial aversive reactions to the flavors (Parker 1995). These dissociations in the impact of different classes of aversive events support the suggestion that a reduction in the voluntary consumption of a taste previously paired with aversive consequences may be motivated by two different processes: taste aversion, where the association of a flavor with nausea leads to acquisition of disgust reactions and a change in the hedonic value of the flavor, and fear-based taste avoidance based on the anticipation of a potential danger as that produced by a novel change in animal's physiological state (Parker 2014).

An alternative method for assessing taste palatability in rats involves analyzing the microstructure of licking behavior during voluntary consumption (Dwyer 2012). The ingestive behavior of rats consuming fluids consists of sustained runs of licks separated by pauses of varying length (clusters), and the mean number of licks in a cluster (lick cluster size) is directly related to the nature and concentration of the solution ingested.

Lick cluster size shows a positive monotonic relationship to the concentration of palatable sweet solutions, while lick cluster size decreases monotonically with increasing concentration of unpalatable quinine solutions. In the context of taste aversion learning, pairing an otherwise palatable taste with nausea results in a reduction of lick cluster size similar to that produced by exposure to quinine. In addition, the pattern of licking behavior is sensitive to changes in the hedonic value of taste stimuli produced by physiological and pharmacological treatments known to modulate palatability in humans. For example, sodium depletion elevates the palatability of sodium chloride, and the administration of benzodiazepines drugs, which increase appetitive responses in the taste reactivity test, enhance lick cluster size. However, while the size of licking clusters is particularly sensitive to changes in flavor palatability, it does not clearly select between disgust-based aversions and fear-based avoidance in the same way as the taste reactivity analysis. Pairing flavors with either pain or drugs of abuse can result in a lowering of lick cluster size, albeit that there are some suggestions that these effects are smaller and more transient than those produced by emetic drugs (Dwyer et al. 2017). These findings reinforce the idea that, while acquired disgust might result in reductions in consumption of particular foods, reductions in consumption cannot be unambiguously attributed to disgust in the absence of careful observation of orofacial behavioral responses directly indicative of that particular emotional response.

## Brain Mechanisms of Disgust

By using brain lesions and electrophysiological and pharmacological techniques, research in affective neuroscience has provided new findings on the brain regions and the neurochemical systems that mediate the hedonic impact of taste stimuli (Berridge and Kringelbach 2015). Neuroanatomical studies have identified a number of cortical (e.g., insular cortex) and subcortical structures (e.g., nucleus accumbens; ventral pallidum) that play critical roles in the hedonic reactivity to taste

stimuli and in the production of hedonic changes during the establishment of a taste aversion. For example, it has been reported that rats lacking gustatory cortex learn to avoid a fluid paired with lithium-induced nausea, but they fail to display disgust (i.e., aversive) reactions as assessed by the taste reactivity method (Kiefer and Orr 1992). Also, it has been found that depletion of serotonin by selective serotonergic lesions of the insular cortex (IC) attenuates the production of disgust reactions to a flavor previously paired with nausea (Tuerke et al. 2012). In addition, studies using *in vivo* optical imaging have found plastic changes in the insular cortex after inducing a reduction in the hedonic value of a taste stimulus by pairing with nausea. Taken together, these findings suggest that the insular cortex mediates the production of affective reactions to taste stimuli.

Other studies have suggested an important role of the nucleus accumbens (NAc) in hedonic reactivity to gustatory stimuli. It has been proposed that the appetitive and aversive value of taste stimuli is encoded by opposite changes in NAc neural activity (Carlezon and Thomas 2009). Specifically, decreased activity of NAc has been related to rewarding events (palatable stimuli), and in contrast, increased activity has been linked with aversive events. This suggests differences in the role of the NAc depending on the nature of the taste stimuli and their hedonic value. Using electrophysiological methods to examine neural activity during the acquisition of a taste aversion, an increase in the firing rate of NAc neurons in response to an intraoral infusion of a previously nausea-paired flavor has been reported (Roitman et al. 2010). Interestingly, a similar shift toward excitatory responses in NAc neurons is observed after the infusion of an unpalatable taste such as quinine. Conversely, the infusion of a palatable sugar solution induces a reduction in firing rate of NAc neurons, suggesting that inhibition of nucleus accumbens activity is associated with positive hedonic reactions to taste stimuli, whereas that excitation is associated to a reduction in the hedonic value or palatability of a taste stimuli.

Finally, the ventral pallidum (VP), which receives projections from the nucleus accumbens,

has been proposed to be a region that can mediate various aspects of reward and to be related to the hedonic impact of taste stimuli. The temporary inactivation of the ventral pallidum induced by pharmacological microinjections eliminates appetitive orofacial reactions to sweet tastes and replaces them with disgust reactions (Ho and Berridge 2014). Moreover, electrophysiological studies have found an increase in the firing rate of VP neurons following the intraoral administration of a sucrose solution but do not respond after the infusion of a concentrated salt solution. However, under a physiological state of sodium deficiency, the VP neurons now respond to the concentrated salt solution with an increase in firing rate similar to that produced by the infusion of sucrose (Tindell et al. 2006). Also, the neural activity in ventral pallidum is reduced when the hedonic value of a sweet taste changes from positive to negative after the establishment of a taste aversion by lithium injections (Itoga et al. 2016). Thus, like nucleus accumbens, activity in ventral pallidum neurons changes in response to the hedonic value or palatability of taste stimuli.

Pharmacological studies have identified several neurochemical systems that modulate the affective reactions to taste stimuli. There is considerable evidence suggesting that opioid neurotransmitter system mediate positive hedonic palatability. Using the taste reactivity method, it has been reported that intracranial microinjections of morphine (a pure opioid agonist) in the medial shell region of nucleus accumbens enhances the number of appetitive orofacial reactions to sweet tastes and reduces disgust reactions to bitter quinine (Pecina et al. 2006). Similarly, the firing rate of VP neurons increases when the hedonic value of a sweet taste is enhanced by opioid stimulation. Interestingly, opioid microinjection into the nucleus accumbens enhances also neural activity in the ventral pallidum, suggesting that these two brain areas act together in a coordinated hedonic circuit (Smith and Berridge 2007). Supporting this functional interaction, it has been found that microinjection of opioid antagonists in either the nucleus accumbens or the ventral pallidum prevents enhancement of appetitive responses to sweet taste. The benzodiazepine system also has

been identified by taste reactivity studies as a mechanism of positive hedonic taste affect. It has been reported that the intracranial administration of benzodiazepine agents (diazepam) enhances appetitive reactions to sweet tastes just as morphine does (Berridge 2000). Conversely, disgust reactions elicited by sucrose are reduced following the temporary inactivation of benzodiazepine receptors in the VP neurons. Finally, it has been suggested a possible role for serotonin system in hedonic reactivity to taste stimuli. For example, the intracranial administration of serotonin receptor agonists in the insular cortex increases disgust reactions and reduces appetitive responses in the taste reactivity test. Conversely, the administration of serotonin receptor antagonists attenuates the production of nausea-induced disgust reactions. Also, reduction of serotonin in the insular cortex by pharmacological lesions interferes with the expression of disgust reactions, suggesting that serotonin is mediating a shift in taste palatability from positive to negative (Tuerke et al. 2012). Recently, it has been reported that endocannabinoids interact with the serotonergic system in the control of disgust reactions. Pharmacological agents that reduce serotonin activation or that activate the cannabinoid system both interfere with the establishment of disgust reactions by emetic drugs (Parker et al. 2011). Taken together, these findings indicate that hedonic reactivity to taste stimuli is mediated by multiple neurochemical systems.

## Animal Models of Disgust in Clinical Settings

Research on animal disgust has contributed not only to know the behavioral and brain mechanisms mediating affective responses to taste stimuli but also provides a useful model for therapeutic treatments for nausea in humans (Rock et al. 2014). Nausea is one of the most distressing symptoms reported by patients receiving chemotherapy treatment for cancer. After receiving several sessions of chemotherapy, patients frequently display a range of learned effects based on the nausea induced by

chemotherapy: these include a loss of appetite and aversion to particular foods as well as the development of anticipatory nausea and vomiting that occurs when the patient return to the clinic for a further session of treatment (Stockhorst et al. 1993). Food aversions and appetite loss following chemotherapy can easily be understood in terms of the acquisition of conditioned disgust to flavors experienced prior to nausea. Moreover, the fact that animal studies have shown that conditioned disgust forms more readily for novel than familiar flavors has already led to the development of the “scapegoat” technique of providing novel foods prior to chemotherapy to prevent the acquisition of taste aversions to the main foods in patients’ normal diets (Andresen et al. 1990). Anticipatory nausea and vomiting may also be explained in terms of conditioned disgust when it is remembered that the complex of cues present in the clinic (e.g., sights, sounds, and smells) can become associated with the toxicosis effects of the chemotherapy drug (Stockhorst et al. 1993). Unfortunately, antiemetic pharmacological treatments (such as ondansetron) that block serotonin receptors reduce acute nausea and vomiting produced by the toxic drug, but they are ineffective in reducing anticipatory nausea and vomiting. Thus, there is an unmet clinical need to develop new therapeutic pharmacological drugs for prevent the side effects of nausea in cancer patients – a need that animal models of disgust can make a valuable contribution to meeting.

It has been demonstrated with the taste reactivity methodology that rats not only display disgust reactions to flavors paired with nausea, but they also display conditioned orofacial disgust reactions to environmental cues previously paired with emetic drugs as lithium chloride (Limebeer et al. 2006). It is important to note that the administration of serotonin antagonists, which attenuates the development of disgust reactions to nausea-paired flavors, does not interfere with the acquisition and expression of disgust reaction to a context paired with lithium-induced nausea (Parker et al. 2006). Therefore, contextually elicited conditioned disgust can serve as model to investigate in animals the antiemetic and

antinausea properties of new drugs. There are preclinical trials in humans suggesting that the administration of cannabinoids may be an effective treatment of chemotherapy-induced nausea (Parker et al. 2011; Rock et al. 2014). For example, the psychoactive component of cannabis, delta-9-tetrahydrocannabinol (THC), reduces acute nausea in rats by its action on cannabinoid receptors CB1 located in the insular cortex. It has been found that THC also attenuates the disgust reactions elicited by context cues paired with nausea (Limebeer et al. 2012). Likewise, other non-psychoactive cannabinoids as cannabidiol (CBD), which does not act at CB1 receptors, reduce contextually elicited disgust reactions in rats, an effect that is reversed by the action of cannabinoid antagonists (Parker et al. 2011). Together, these findings show that the rat model of anticipatory nausea provides a valuable tool for evaluating the effectiveness of antinausea treatments.

## Conclusion

Disgust in nonhuman animals is both real and readily measured through the observation of orofacial reactions. Studies of acquired disgust in laboratory rodents have made a considerable contribution to the understanding of the basic behavioral and brain mechanisms underpinning this process. Moreover, conditioned disgust provides a valuable model for investigating nausea and vomiting in clinical settings. Behavioral interventions have already been developed based on these animal models to reduce chemotherapy-based food aversions, and future pharmacological interventions for anticipatory nausea and vomiting are currently being assessed.

## Dishabituation

Juan M. Rosas

Universidad de Jaén, Jaén, Spain

### Definition

Dishabituation is defined as the immediate restoration of responding to a habituated stimulus that follows the presentation of a non-habituated stimulus.

### Introduction

The term habituation is used to describe the decremental effect of repeated presentations of the same stimulus upon the reflex response that this stimulus originally elicited. Habituation has been reported in a wide range of organisms, from single-celled animals to primates (Tighe and Leaton 1976). Once responding to a stimulus is habituated, presentation of a different stimulus right before presenting the stimulus that is already habituated results in a restoration of the habituated response to the original stimulus that it is called dishabituation (Thompson and Spencer 1966). The dishabituation phenomenon is one of the phenomena that allows for differentiating habituation from other decremental processes of behavior unrelated to learning such as fatigue.

Thus, dishabituation is found as a recovery of responding to a habituated stimulus as a consequence of presenting a new, different stimulus before the presentation of the original one. The amount of dishabituation decreases upon repeated presentations of the dishabituating stimulus in a phenomenon called habituation of dishabituation (Thompson and Spencer 1966). The fact that dishabituation disappears when the dishabituating stimulus habituates suggests that the dishabituating stimulus should be somehow unexpected and that it loses its power as novelty disappears (Rankin et al. 2009). Traditionally, the stimulus used to produce dishabituation has been a strong one, though some reports in the

literature show that at least in some cases the use of a weak stimulus may play even a better role as a dishabituating stimulus than a strong one (Marcus et al. 1988).

### Theoretical Approaches

Dishabituation has been traditionally explained within the framework of the dual-process theory of habituation (Groves and Thompson 1970; Thompson 2009). This theory assumes that two independent processes underlie responding to repeated stimulus presentations: A habituation process affecting the reflex-arch that mediates response decrements, and a sensitization process affecting the general state of the organism that mediates response increments. These two processes combine to produce the observed behavior. Dual-process theory of habituation suggests that dishabituation is caused by the superposition of an increase of a general responsiveness of the organism produced by the added stimulus (sensitization) that does not disrupt the process of habituation to the original stimulus, but reduces the general threshold for responding, facilitating the observation of the habituated response to the original stimulus.

The interpretation of dishabituation as an independent facilitation superimposed upon habituation suggested by the dual-process theory of habituation has accrued an important support over years of research in both, human (e.g., Kaplan and Werner 1986) and nonhuman animals (e.g., Carew et al. 1971; Kandel 1976). However, recent research seems to suggest that, at least within the field of the electrodermal orienting reflex in humans, dishabituation may also involve a disruption of the habituation process, with magnitude determined by the current arousal level (Steiner and Barry 2014). This is in agreement with the idea that dishabituation being considered as a disturbance of the habituation process as suggested by Sokolov (1963) in his neural-model comparator theory. However, these isolated results do not compromise the idea that, in general terms, dishabituation is due to the sensitization produced by presentation of the new stimulus

rather than by a disruption of the habituation process that seems to remain intact in most cases.

## Conclusion

Dishabituation, understood as the response recovery from habituation that follows the presentation of a non-habituated stimulus (dishabituation) is a broad phenomenon found in a wide range of species, and it seems generally due to the non-habituated stimulus increasing the general level of arousal of the organism (sensitization).

## Synonyms

[Dispersal mechanisms](#)

## Definition

The ability of an individual to relocate in order to acquire the resources needed for reproduction and survival.

## Introduction

Dispersal ability is measured by the ease with which an animal can move to acquire the resources needed for reproduction and survival (Tschamtkke et al. 2002). Ability is based on environmental pressures and the locomotive capabilities and adaptations of the species (Sekar 2012). Dispersal ability influences the geographic range of animals historically, as different ecological barriers impact species differently depending on their locomotion (Lester et al. 2007). With an increase in habitat fragmentation and the impact of climate change, the dispersal ability of a species is critical to determining survival of a population (Sekar 2012).

## Locomotive Capabilities

Animal locomotive abilities help to shape dispersal ability by determining the distance and habitat type that can be traversed (Croteau 2010; Cushman and Landguth 2012). For example, the dispersal ability of an island-dwelling individual that cannot swim or fly will be limited by the ocean barrier. Dispersal can be divided based on locomotive capabilities to active dispersal and passive dispersal (Croteau 2010).

**Active dispersal** is when animals disperse through their own locomotion. The larger the dispersal distance, the higher the dispersal ability (Croteau 2010). Flight gives many animals including birds, bats, and butterflies highly efficient dispersal ability, as they can travel larger distances and overcome barriers (Croteau 2010; Sekar 2012). In many marine animals, especially fish, dispersal occurs during the larval stage (Lester et al. 2007); however, active dispersal can occur in the adult period in other animal species (Croteau 2010).

**Passive dispersal** is when immobile or mobile animals disperse using disseminules through other vectors. This is common in aquatic invertebrates such as corals and sea anemones (Croteau 2010). Disseminules disperse through environmental vectors such as wind or by attaching themselves to other mobile animals (Croteau 2010).

There can also be a mobile larvae stage in which juveniles of a species are able to disperse to new areas by drifting to the surface and traveling on the water current (Grantham et al. 2003; Croteau 2010). This mobile larvae dispersal method can be seen in pelagic fishes and zooplankton (Lester et al. 2007).

## Habitat Connectivity and Quality

Habitat fragmentation can negatively impact the dispersal ability of a population by limiting the gene flow between populations separated by disconnected patches (Cushman and Landguth 2012). In general, larger animals are able to travel longer distances and cross larger barriers to maintain a higher degree of population connectivity (Cushman and Landguth 2012). Locomotion can mitigate the negative influence of habitat fragmentation on dispersal ability as flying animals are able to travel over some of the barriers that limit terrestrial animals (Croteau 2010). In contrast with recently changed and fragmented habitats, highly stable environments can result in the evolution of a lower dispersal ability (Lester et al. 2007). For example, some insects will lose their flight capabilities at higher altitudes resulting in lower dispersal ability (Wagner and Lieberr 1992).

## Conclusion

If locomotive capabilities are essential for determining the dispersal distance, then habitat quality and connectivity are the limiting factors to dispersal ability (Croteau 2010; Cushman and Landguth 2012). If the barriers to dispersal are restrictive enough to prevent dispersal from occurring, the result may be habitat loss and eventual population extinction (Cushman and Landguth 2012).

## Dispersal Mechanisms

### ► Dispersal Ability

## Dispersal Patterns

Keely Q. Maynard  
Oxford Brookes University, Oxford, UK

### Definition

Patterns of how and when individuals disperse within and between populations.

### Introduction

Dispersal is any movement of an animal from one location to another that has a chance of impacting gene flow (Ronce 2007). Dispersal can be divided

into two categories: **natal dispersal** when a juvenile leaves the parental range for a new area and **breeding dispersal** when an adult animal moves to a new area to increase breeding success (Clobert et al. 2012). Due to the dangerous nature of dispersal – the mobile individual has a higher risk of mortality during the dispersal period – the benefits must outweigh the fitness costs (Ronce 2007). Most importantly, dispersal allows for gene flow which maintains healthy, genetically diverse populations. This is essential for the survival of species in fragmented habitats (Clobert et al. 2012). Dispersal patterns define how and when individuals disperse within and between populations and may be affected by ecological composition, population demographics, and the individual (Clobert et al. 2012).

### Conditional and Unconditional Dispersal

There are two other dispersal patterns: conditional and unconditional dispersal. **Conditional dispersal** is a common pattern characterized by an individual only dispersing in response to pressures such as a lack of resources, increased mate competition, or excess population which forces the individual out of the natal range (Fattebert et al. 2015; Clobert et al. 2012; Gros et al. 2008). Conditional dispersal based on excess population is also referred to as density-dependent dispersal whereby the habitat fragment or patch is incapable of supporting the current population size (Fattebert et al. 2015; Clobert et al. 2012). **Unconditional dispersal** is the simplest form of dispersal (Gros et al. 2008). Based on the theory of inbreeding avoidance, individuals will leave the natal range at a constant rate, independent of resource availability, habitat quality, and population size, to avoid mating with kin (Fattebert et al. 2015; Gros et al. 2008).

### Sex-Biased Dispersal Patterns

Sex-biased dispersal patterns – when only one sex disperses – can be explained by inbreeding avoidance and kin competition levels (Ronce 2007).

In other words, if a single sex disperses, there is little chance of breeding between siblings (Gros et al. 2008), and there is little chance of competing with kin for resources/mates (Ronce 2007). Sex-biased dispersal patterns can also result when there is a difference in dispersal cost between the sexes. The sex with a lower dispersal cost should disperse at higher levels (Gros et al. 2008). Mate competition or competition for reproductive resources can also lead to sex-biased dispersal if there is a higher level of competition for one sex (Gros et al. 2008).

## Change to Patterns over Time

Dispersal is impacted by both ecological conditions and demographic differences resulting in patterns that can change over time (McPeck and Holt 1992). In leopard populations, where the group size fluctuates with human activity, male dispersal distances and timing have changed with males relocating next to their parental home range instead of dispersing farther away (Fattebert et al. 2015). Males will settle closer to related females, potentially increasing the rate of inbreeding and negatively impacting the genetic health of the population (Fattebert et al. 2015). Environmental changes can also influence dispersal patterns, causing them to evolve to reflect the new ecological conditions (McPeck and Holt 1992). Slow growth populations, such as density-dependent dispersers that engage in contest competition for resources, may struggle to adapt to habitat pressures caused by climate change or human activity. Their low population levels and slower growth rates will result in lower dispersal rates and reduced habitat connectivity and gene flow (Best et al. 2007).

## Current Methods

Dispersal patterns can be determined through indirect and direct methods. **Direct methods** such as tracking devices – GPS radio collars, mark-recapture, individual marking, and live trapping – are used to measure animal movement

between and within populations (Croteau 2010). These methods are both expensive and labor intensive and often result in a smaller sample size due to individual death (Croteau 2010). Genetic analysis is used in **indirect methods** by providing information on gene flows between and within populations to identify alleles and genetic markers. Patterns in genetic markers can infer relatedness and allow for a larger sample size than through direct methods (Croteau 2010). Despite these advantages, indirect methods do not provide any conclusive information on behavior (Croteau 2010).

## Conclusion

Dispersal patterns vary spatiotemporally as different populations experience unique ecological pressures that result in the evolution of varying dispersal patterns (Clobert et al. 2012).

## Displays

Jen Muir  
Department of Social Sciences,  
Oxford Brookes University,  
Oxford, UK

### Definition

Displays are ritualized behaviors performed by an individual in order to communicate information to another.

### Introduction

Communication is a vital feature in the lives of animals. It involves an individual relaying information to others with the intent of changing their behavior. Receivers of this information may be of the same or of a different species to the signaller. Displays are repeatedly used patterns of signals which over time have evolved to become more conspicuous, often losing their original function and simply acting to communicate information (Smith 1977). These behaviors show a wide degree of variation in their

presentation and intention. Displays may be visual, chemical, vocal or postural, or multimodal and serve to communicate information relating to an individual's territory, fitness as a potential mate, or parent-infant interactions. Displays may also be used to deceive or intimidate predators. This entry reviews the contexts in which displays are used, various forms of displays across taxa, what impacts on their use, and how these behaviors evolved in detail.

### Antagonistic

Many displays are used in antagonistic situations, such as defending a territory, to dissuade predation, or in relation to conflict with other members of the same species. Some species use displays to defend their territories. This has been seen in territorial male goitered gazelles, *Gazella subgutturosa*, which roar and press horns during encounters with other males (Blank et al. 2015). The authors suggest these displays may function to communicate male endurance, avoiding the need for fighting during a time of decreased body mass and increased mortality for males. When fights do occur, many species perform post-conflict displays. Grafe and Bitz (2004) observed post-conflict victory displays after conflicts between pairs of tropical boubous, *Laniarius aethiopicus*, proposing that these vocal displays are used to show their victory to other pairs nearby. On the other hand, those who lose conflicts may use displays to try to appease their opponent. An example of this behavior can be seen in crayfish, *Orconectes rusticus*, which whip their antennae to appease dominant individuals after conflicts (Bruski and Dunham 1990). Displays can also be used to communicate information about an individual's social ranking within a group. Oystercatchers, *Haematopus ostralegus*, perform displays involving piping calls in order to maintain their position within the dominance hierarchy. These displays were used by lone birds in order to maintain feeding ranges and in groups to contest these areas (Ens and Goss-Custard 1986). Additionally, high-ranking individuals used a “butterfly flight” in

which they circled an area before landing (Ens and Goss-Custard 1986). When threatened by a predator, some species use deimatic displays to scare off potential attackers. Species using these displays are often camouflaged or mimicking another species or inanimate object, for example, mountain katydids, *Acripeza reticulata*, raise their wings and expose the bright colors on their body in order to shock predators (Umbers et al. 2015). Overall, displays are used to communicate a variety of messages in antagonistic situations, including territory ownership, social ranking, appeasement, and victory, as well as to avoid predation and physical confrontations.

## Mating

Courtship displays consist of a multimodal collection of behaviors which are performed in order to attract or maintain a mate. These displays are usually seen in male individuals; however, they may also be performed by females, or by both sexes in mutual displays. Additionally, both socially monogamous and polygamous species have been recorded using courtship displays. These displays are thought to act to allow for the recognition of individuals of the same species and opposite sex. This can be seen in the male courtship songs of fruit flies, *Drosophila* sp., in which song traits such as length and frequency of song pulses differ between species (Saarikettu et al. 2005). Another function is to synchronize mating behaviors, stimulating females to mate in species that do not take environmental cues for breeding. For example, male wolf spiders, *Stegodyphus lineatus*, perform vibrating behavior in order to encourage mating (Maklakov et al. 2003). Similarly, shuddering behaviors in male orb-web spiders, *Argiope keyserlingi*, serve to help prevent cannibalism from the female during mating (Wignall and Herberstein 2013). In female courtship displays, behaviors are suggested to honestly indicate an individual's reproductive potential and proximity to spawning time, as is seen in the rush and twitching displays of the Banggai cardinalfish, *Pterapogon kauderni* (Kolm 2004).

The mutual courtship displays of socially monogamous blue-capped cordon-bleus, *Uraeginthus cyanocephalus*, involve calling and dance behaviors and are suggested to have several functions. One purpose is to advertise the pair bond and signal commitment to others of the same species, while on the other hand may also serve to find mates outside of the pair (Ota et al. 2015). Overall, courtship displays are found across various species and can be performed in many different forms such as song and movement. These displays may serve multiple purposes such as species recognition, synchronization of mating, advertising reproductive potential, or reinforcing pair bonds.

## Parent-Offspring Interactions

Displays from offspring aimed at their parents are often seen in bird species, typically when requesting food. These displays often involve posturing, exposing colored mouth gapes, and repeated calling from nestlings. It is suggested that this display functions to resolve parent-offspring conflicts, in which an individual nestling aims to receive more investment from the parents than current siblings (intra-brood conflict), as well as future broods (inter-brood conflict) (Trivers 1974). To accomplish this, displays may act to persuade parents to offer more food to the nestling through signalling that they are in good condition and so worth extra investment, or by showing an honest need for food. Examples of these displays can be seen in nestling tree swallows, *Tachycineta bicolor*, which posture more intensely in relation to increased hunger, resulting in preferential feeding from the parents (Leonard et al. 2003). They also found that nestling calling rates related to where nestlings were located in the nest, with higher rates from those in more difficult to reach positions for parents, possibly to attract their attention. In barn swallows, *Hirundo rustica*, hungry nestlings called more often, and those in good condition called at a lower frequency (Sacchi et al. 2002). Displays exposing nestling mouth gapes are also proposed to suggest nestling condition, as those in better health are able to devote more resources to maintaining a

brighter gape (Saino et al. 2000). Other forms of display include wing shaking and gape-colored patches on the wings of brood-parasitic species such as the Horsfield's hawk-cuckoo, *Hierococcyx hyperythrus*. It is suggested that wing shaking may serve as an indicator of nestling condition, while wing patches may function to imitate the gapes of several nestlings, encouraging more feeding from parents (Tanaka and Ueda 2005; Grim 2008). Components of begging displays are thought to act together to communicate various aspects of nestling condition, such as the intensity of hunger and quality of the individual begging.

### Influences on Display Behavior

Several factors can affect the use of displays. Many of these influences are environmental, such as wind, light levels, distance from receiver, and perceived predation risk. Peters et al. (2007) found that the Jacky lizard, *Amphibolurus muricatus*, perform their aggressive tail flick displays for longer and in an intermittent pattern in stronger wind conditions. They propose that this may be due to the lizards timing their flicks for visibility among moving plants, increasing the likelihood that their display is seen by the receiver. Male guppies, *Poecilia reticulata*, use a visual display involving colored spots of varying sizes in courtship. When light levels within the streams they occupy are low, males reduce their distance to females in order to best show spot contrast and brightness, which are features preferred by females (Long and Rosenqvist 1998). Distance is an influence for male fiddler crabs, *Uca perplexa*, during their claw-waving courtship display, in which they shorten the duration and lateral movement involved in the display with reduced distance to females. This is suggested to reduce the energetic cost of displaying and appear less aggressive (How et al. 2008). Similarly, distance is a factor for male zebra finches, *Taeniopygia guttata*, who perform their vocal courtship display at a higher amplitude when females are further away in order to best transmit the signal (Brumm and Slater 2006). Another environment factor

is predation risk. Su and Li (2006) found that when female jumping spiders, *Jacksonoides queenslandicus*, perceive a higher risk of predation, both courting males and females respond by reducing the duration of their displays. Additionally, male túngara frogs, *Engystomops pustulosus*, were found to reduce the rate and amplitude of mating calls when confronted with a model predator (Ryan 1985). Social factors can also influence how displays are used. In whitethroats, *Sylvia communis*, courting males perform a display involving vocal and diving components. Female calls (dscharps and ze-calls), as well as short jumps around males have been observed to influence their display, causing an increase in songs and copulation (Balsby and Dabelsteen 2002). Brooke et al. (2000) examined the effect of others on the calling of ornate nursery frogs, *Cophixalus ornatus*, finding that males would use the calling of others to determine when they should call. Social facilitation of displays has also been seen in lesser short-tailed bats, *Mystacina tuberculata*, in which lekking males displaying alone would sing more than those in groups (Toth et al. 2018). An individual's physical features can also play a role in display behavior. Male dunlins, *Calidris alpina*, display more frequently and spend more of their displays hovering when they have a smaller body size (Blomqvist et al. 1997). In conclusion, displays are complex behaviors which can be affected by several factors, including environmental, social, and physical influences.

### Evolution of Displays

There are multiple theories as to how these display behaviors evolved over time across various contexts. For antagonistic displays between members of the same species, the cost of a physical fight is suggested to be the cause for their evolution. Displays offer an opportunity to weight up the likelihood of winning a physical fight and allow for avoiding a fight completely (Maynard Smith 1982). Deimatic displays are thought to have co-evolved alongside predator behaviors, developing the display in response to predators

becoming better at seeing through the first level of defense that species has, for example, camouflage (Umbers et al. 2015). Sexual selection is believed to have played a role in the evolution of courtship displays, with two main hypotheses to suggest how. One proposes that displays communicate good genes and so are chosen as mates in order to pass these onto offspring (Maynard Smith 1991). The other suggests that it is instead the display itself that is chosen, as this makes them appealing mates (Fisher 1930). Nestling begging displays are thought to have evolved due to competition between siblings, as displays increase in intensity and frequency with increased competition (Kim et al. 2011). On the other hand, other studies suggest that begging displays evolved to honestly communicate nestling condition, which in turn allows parents to invest the optimal amount of time in that individual (Sacchi et al. 2002). In terms of specific behaviors, Grim (2008) hypothesizes that nestling display behaviors such as wing shaking developed from behaviors shown during restlessness and over time became ritualized for begging. Overall, there are several evolutionary paths that led to the development of display behaviors, many of which are not yet fully understood.

## Conclusion

In conclusion, animals across multiple taxa use behavioral displays in order to share information with others, including amphibians, reptiles, birds, arthropods, and mammals. Displays may be used in antagonistic, mating, and parent-offspring interactions, involving visual, vocal, postural, or chemical signals. In many cases, such as nestling begging displays, multiple modes of signalling are used to communicate with the parents. Additionally, these displays can be influenced by factors within the environment such as predation risk, light levels, wind conditions, and distance to receiver. Social influences can also impact on and facilitate display behaviors. These can affect how long or intense displays are in an effort to best communicate to a receiver. There are currently several hypotheses on how and why displays

have evolved, including as a mechanism to avoid physical confrontations and predation, communicate good health and genes, and deal with sibling competition. However, there is still further research needed to fully understand the evolutionary mechanisms behind display behaviors.

## Disruptive Coloration

Thomas E. White

School of Life and Environmental Sciences, The University of Sydney, Sydney, NSW, Australia

## Definition

A set of markings that creates the appearance of false edges and boundaries and hinders the detection or recognition of an object's, or part of an object's, true outline and shape.

## Introduction

The threat of predation has driven the evolution of diverse anti-predator adaptations in nature, of which camouflage – or concealment – is widespread. One striking form of camouflage is disruptive coloration, in which contrasting markings

are used to break up and obscure an object's appearance. First alluded to by the naturalist Poulton (1890), and later formalized by Thayer in *Concealing Coloration in the Animal Kingdom* (1909) and Cott in *Adaptive Coloration in Animals* (1940), the efficacy of disruptive coloration has been convincingly demonstrated across the natural world. From the banded wings of tropical butterflies, to the bold spots of isopods, to the changeable patterns of cuttlefish (Merilaita 1998; Hanlon et al. 2009), the study of disruptive coloration has advanced our broader understanding of adaptive coloration and predation-prey interactions and has also inspired developments in human technologies.

## Mechanisms

Disruptive coloration functions by creating the appearance of false boundaries (Stevens and Cuthill 2006). This may occur both within an object to disrupt its internal shape or at its edges to confuse the distinction between an object and its background. Numerous sub-principles have been proposed that detail the mechanisms underlying the efficacy of disruptive coloration, though five appear to capture the key processes of interest (Stevens and Merilaita 2009), namely:

1. *Differential blending* occurs when parts of a color pattern match the viewing background, while others are strongly contrasting, thereby breaking up an object's contours.
2. *Disruptive contrast* describes the use of highly conspicuous, contrasting pattern elements set adjacent to one another, with the expectation that a higher degree of contrast will be more effective in inducing disruptive effects.
3. *Disruption of surface through false edges* occurs when contrasting internal markings generate illusory boundaries on the surface of an object, thereby masking its true shape.
4. *Disruptive marginal patterns* are those which make contact with an object's edge, to blur the distinction between parts of an object and its background and/or generate the impression of discontinuity.
5. *Coincident disruptive coloration* describes the geometry of disruptive color pattern elements, which may spread across distinct body regions to confuse the otherwise clear boundary between them.

These principles are nonexclusive and typically act in concert to achieve their full effect. Marginal patterns, for example, are often combined with differential blending, to engage the viewing background itself in breaking up an object's form (Cuthill et al. 2005). Similarly, coincident disruptive coloration is particularly effective in conjunction with strong disruptive contrast, to both mask the boundaries between regions and the overall form of an object (Barry et al. 2015).

## Technological Applications

Like so much in the natural world, the cryptic color patterns of animals have served as inspiration for varied applications in human affairs. The work of Thayer (1909) directly inspired early efforts at military camouflage during World War I, and disruptive patterns are now a defining feature of many military uniforms (Newark et al. 2002). As in nature, however, the use of such a strategy has proven challenging under dynamic real-world conditions, as the efficacy of disruption is severely reduced, for example, against variable backgrounds, while in motion or in unfavorable viewing conditions. And just as an animal's visual camouflage is less effective against predators that draw on diverse sensory input, the development of radar has rendered the use of disruptive coloration largely redundant for larger-scale military structures, such as planes and ships. More recent efforts have also seen the principles of visual disruption applied to everyday situations, such as in conspicuously colored "shark-repellent" wetsuits and surfboards. These rely on boldly contrasting patterns to inhibit the identification of swimmers as potential food sources by sharks which, incidentally, are largely color-blind.

## Conclusion

Disruptive coloration hinders the detection and recognition of an object's form by creating false internal and/or external boundaries with contrasting markings. It is a common mode of camouflage in nature and is a highly active area of research in the study of adaptive coloration.

## Definition

Diurnality is a type of daily (or diel) activity pattern in which most of the activity occurs during the light hours of the day.

## Introduction

A day in an animal's life typically alternates states of rest and activity. A variety of behaviors are performed when the animal is active, such as foraging, territory defense, exploration, and mating. The time when activity occurs is crucial to an animal's survival, since these are the moments in which it is most vulnerable to predators and harsh weather conditions. The alteration between the states of activity and rest during the 24-h daily cycle results in a temporal pattern called daily, or diel, activity pattern (Halle and Stenseth 2000). These patterns are commonly classified as diurnal (i.e., most of activity occurs during the light phase of the day), nocturnal (i.e., most activity occurs during the dark phase of the day), crepuscular (i.e., most activity occurs during dawn and dusk), and cathemeral (i.e., activity occurs during both light and dark phases of the day) (Daan 1981).

Daily activity patterns are accompanied by daily rhythms in many physiological variables. Diurnal animals not only allocate most of the behavioral activity during the light hours of the day, but it is also during this phase of the day that they display higher body temperature, higher heart rate, higher digestive function, and peak of hormones such as glucocorticoids.

## Physiological Mechanisms Behind Diurnality

The 24-h rhythmicity of behaviors and physiological processes is not merely a reaction to daily environmental cycles, such as light intensity, temperature, or food availability. This rhythmic expression persists even when the organism is exposed to conditions in which all environmental variables are held constant. In this situation, the period of the expressed rhythm (i.e., the interval of time each cycle takes to complete) is always different, although close to 24 h, which is why this rhythm is called circadian, a Latin term meaning "around one day." Persistence under constant conditions is evidence that these rhythms are generated endogenously by circadian oscillators (Moore-Ede et al. 1982).

Circadian rhythms are present in all taxa of living beings, from protists to multicellular eukaryotes (Dunlap et al. 2004). The basic structure of the circadian system in animals consists of a circadian oscillator, which generates the rhythm; efferent pathways, which transmit the rhythmic signals of the oscillator to the various organs and tissues of the organism; and afferent pathways, which receive, process, and transmit the temporal information from the environment to the oscillator (Moore-Ede et al. 1982).

In mammals, the central circadian oscillator is located in two small hypothalamic nuclei located above the optic chiasm, the suprachiasmatic nuclei (SCN). The daily light-dark cycle is the main environmental cycle involved in the synchronization of the circadian oscillator. Light is perceived by the retina, which has direct nervous projections to the SCN, through the retinohypothalamic tract. The SCN have many nerve projections to other areas of the hypothalamus and the brain and chains of neurons connecting them to peripheral organs. These projections can serve as efferent nerve pathways, which transmit the oscillator signals. In addition to these pathways, there is also evidence of neurosecretory efferences (Dunlap et al. 2004).

Despite the opposite temporal patterns in behavior that define diurnality and nocturnality, the neural activity of the SCN of diurnal mammals is very similar to the one in nocturnal mammals, with the highest metabolism and electrical activity always occurring during the light hours of the day (Yan et al. 2018). This similarity suggests that the mechanism defining the timing of behavioral activity (i.e., diurnality or nocturnality) occurs downstream from the central circadian oscillator. To date, evidence indicates that there is no single "switch" controlling the timing of activity, but rather diurnality results from the interrelationship of several mechanisms in the efferent pathways from SCN that regulate behavior and physiology (Yan et al. 2018).

## Evolutionary Aspects of Diurnality

Diurnality is widespread among all major groups of animals. In vertebrates, it is the predominant

activity pattern in fish, reptiles, and birds. Mammals and amphibians, on the other hand, are predominantly nocturnal (Daan 1981). The switch to nocturnality in mammals is believed to play an important role in the radiation of mammals in the Mesozoic, according to the “nocturnal bottleneck” hypothesis (Gerkema et al. 2013). Nevertheless, diurnality reappeared, independently, in several groups of mammals. Recent phylogenetic studies suggest that diurnally started to resurface in mammals during the Cenozoic, with simian primates being among the earliest mammals to be diurnal (Maor et al. 2017).

There are several morphological and physiological specializations related to diurnality. Many of them involve the visual system, such as eye size and shape; high concentration of ascorbic acid in the eyes, which protects them from solar radiation; and photoreceptor distribution in the retina, which usually has more cones in diurnal animals than in nocturnal ones (Kronfeld-Schor and Dayan 2008). Other specializations include dark pigmentation of the skin and physiological adaptations related to maintenance of the water balance, specially in desert animals.

## Flexibility of Activity Patterns

Characterization of a species as diurnal seems straightforward under controlled, narrow, laboratory conditions. This standard characterization, together with anatomical and morphological specializations, can lead to the conclusion that diurnality is an inherent and fixed characteristic of the species. However, activity patterns are much more plastic in nature. Many species that are classified as nocturnal because of their activity pattern under standard laboratory conditions switch to diurnality when exposed to a variety of environmental and social factors, such as energetic challenges, changes in light intensity, introduction of a running wheel, and presence of inter- or intraspecific competitors and predators (Hut et al. 2012). Switches of typically diurnal species to nocturnality can also occur in response to high ambient temperatures, competitors, or predators. Moreover, many species switch their

activity patterns across seasons, being diurnal in the winter and nocturnal during summer, for example (Levy et al. 2019).

## Final Remarks

Diurnality is a widespread activity pattern in the animal kingdom. Nevertheless, classifying an animal as diurnal is not straightforward, since many species switch their activity patterns under certain environmental conditions. Although characterization of activity patterns in natural settings is challenging due to the need of continuous measurement of activity during several days, it can shed light on the ecological and evolutionary significance of diurnality and the flexibility of activity patterns.

## Divergent Evolution

Pallavi Gautam

Centre of Advanced Study in Botany, Institute of Science, Banaras Hindu University, Varanasi, Uttar Pradesh, India

### Definition

Divergent evolution represents the evolutionary pattern in which species sharing a common ancestry become more distinct due to differential selection pressure which gradually leads to speciation over an evolutionary time period.

### Introduction

Earth as we see today in its present form with diverse life forms is the result of evolution that has been in action since its inception. Evolution is the biological process through which

characteristics of a species changes gradually over time with the help of the forces of natural selection (Gregory 2009). It is a common belief that all the life forms that exist have gradually developed from a single common ancestor through the process of evolution (Ashraf and Sarfraz 2016). The main driving force behind evolution is better adaptation and reproductive success of species in its changing environment. Genetic variations present within the populations acts as a raw material on which various forces (like natural selection, genetic drift, etc.) act that results in a gradual change in the characteristics of present forms from their ancestors. The ultimate source of these variations is mutation and genetic recombination (Barton 2010). The process of evolution is dynamic and occurs at different rates and patterns. The mechanisms that are instrumental in evolution process are natural selection, genetic drift, gene flow, and biased mutation (Ashraf and Sarfraz 2016). Under the influence of differential selection pressure, evolution over time follows several different patterns which forms the basis for its classification. Based on this four main types of evolution are: divergent, convergent, parallel, and coevolution (Stearns and Hoekstra 2000). When organisms belonging to two or more lineages evolve similar features independently in an attempt to adapt to similar environmental conditions or same selective pressure, the evolutionary process in action is Convergent evolution (Stayton 2015). Wings of insects and of birds (analogous structures) are an example of convergent evolution. Parallel evolution is the evolutionary process through which different species belonging to closely related lineages show evolution of similar traits/attribute in an independent manner while adapting to the same kind of environmental selection pressure (Bailey et al. 2017). Parallel evolution is exemplified by the similarity between marsupials of Australia and placental mammals of other continents. Coevolution is instrumental when closely interacting species exert selective pressures on each other, as a result they adapt and evolve together. Most common examples include prey-predator relationship, host-parasite interaction, and symbiotic relationship (Thompson 2010).

The term divergent evolution was first introduced by J. T. Gullick. Divergent evolution occurs when differential selection pressure or evolutionary driving force (both biotic and abiotic) acts on a subgroup of species which leads to accumulation of variations that favors better adaptation (Schluter 2001). The buildup of these adaptive traits makes this subgroup more and more distinct from their ancestor. Thus, divergent selection eventually leads to speciation over an evolutionary time period (Rundle and Nosil 2005). Divergent evolution is mandatory to achieve best chances of survival in changing environment. In the consecutive sections, various aspects associated with divergent evolution are covered in detail.

## Forces Behind Divergent Evolution

Divergent evolution or evolutionary branching occurs in response to selective pressure like changes in biotic factors (e.g., species interactions) and abiotic factors (environmental factors like climate, nutrient status, physical structure, and niche divergence) which drive natural selection. These sources have been discussed in detail under separate headings (Schluter 2001).

### Species Interactions

The major biotic factor that leads to divergent selection is inter- and intraspecific interactions among organisms present mainly in sympatric populations. Species interactions in the form of competition, predation, mutualism, etc., play role in divergent evolution (Doebeli and Dieckmann 2000). However, they may or may not lead to speciation. Many studies suggest that interspecific competition is the predominant factor playing role in divergent evolution (Schluter 2001; Rundle and Nosil 2005). Weak species interactions do not play much role in evolution dynamics; however, they can bring about minor changes in population sizes (Barracough 2015). Strong species interactions are major players that bring about profound changes in evolution dynamics. Various positive (commensalism, symbiosis) and negative (competition, predation) species interactions

among different organisms in a community alters population size and in doing so also alters evolutionary rate. Smaller populations show lesser adaptability in changing environmental conditions leading to greater fluctuations and size reduction whereas huge stable populations adapt better and show better reproductive fitness bringing about change in evolutionary outcomes (Johansson 2008). Species interactions can also lead to co evolution across communities due to selection pressure on species by mutualists, predators, and competitors. Species interaction works synergistically with abiotic pressures (environmental changes) and promotes evolutionary responses with the help of ecological network.

### Environmental Differences

Various abiotic stresses in the form of changing environmental conditions are one of the primary sources of divergent evolution (Schluter 2001). Divergent selection normally arises among populations of same species allopatrically separated in different environmental conditions or in populations (sympatric) inhabiting different niche existing in the same geographical region (Mayr 1947). While adapting to these differing environmental gradients (climate, available resources, physical structure, etc.), different populations might develop barrier to gene flow and become reproductively isolated over an evolutionary time period leading to speciation (Nagel and Schluter 1998). Some species respond better to a certain environmental condition by the virtue of specific phenotypic traits whereas their fitness reduces in another environment, insinuating divergent selection in action (Rundle and Nosil 2005).

### Sexual Selection

Sexual selection is another potent source behind divergent evolution. It is a constituent of natural selection and arises due to variability in fertilization rate (Ritchie 2007). Sexual selection can act as a powerful evolutionary source in achieving reproductive isolation as it directly interacts with traits associated to mate recognition (Panhuis et al. 2001). The reason behind sexual selection is that in a population, individuals exhibit differential reproductive success due to variation in

secondary sexual characteristics and mating choices. Thus, sexual selection might contribute to speciation by achieving divergence in mating choices and signals (Panhuis et al. 2001). In certain scenarios sexual selection might lead to co-evolutionary divergence of traits that mutually influence partner's evolution (e.g., female select mate on the basis of their mating signals) (Ritchie 2007). Sexual selection can lead to divergence within isolated populations either independently or synergistically along with environmental differences (Ritchie 2007).

### Natural Selection

The most crucial process of evolutionary change that is responsible for the adaptability of living world is natural selection (Gregory 2009). The differential selective pressures discussed in the section above drive natural selection and compel the organisms to evolve. In order to adapt to varying conditions generated by selective pressures (environmental differences, species interaction, and sexual selection), organisms change and through the mechanism of natural selection, trait fittest for the survival of organism is selected and propagated further. It increases the frequency of genetic traits that are better suited to natural environment and eliminates the less suited ones. The origin of genetic variant through mutation is a random and directionless process; however, their propagation in next generation through natural selection is nonrandom and directional due to its pivotal role in survival and reproduction (Gregory 2009). Natural selection leads to differential survival among organisms of same species and is carried out in three ways namely directional, stabilizing and disruptive selection (Losos 2017). Under changing environmental condition when either one of the extreme phenotype is favored or average is eliminated, selection is directional and it changes the mean value of the population's trait. An example of directional selection is industrial melanism. Similarly, when both the extreme phenotypes have greater fitness and intermediates or average phenotypes are eliminated, selection is known as disruptive selection. It leads to fragmentation of population into various adaptive forms and may lead to speciation (Boddum 2008). On

the contrary, stabilizing selection favors intermediate or average phenotypes and eliminates extreme phenotypes, thereby increasing homozygosity in nonvariable environment (Boddum 2008).

### Evidence of Divergent Evolution

A better understanding of the process can be developed by studying the examples of divergent evolution.

#### Darwin's Finches and Adaptive Radiation

Divergent evolution is best exemplified and discussed through the study of Darwin's Finches. Darwin's finches actually show adaptive radiation which is a form of divergent evolution. It was Darwin who first introduced the concept of adaptive radiation. The process through which a recent ancestral species diversify into a number of descendant species while adapting to changing environmental conditions like availability of new resources or new niches (niche divergence) is known as adaptive radiation (Losos and Mahler 2010). Through the process of speciation and phenotypic adaptation species with different physiological and morphological traits evolve from a recent common ancestor. Adaptive radiation deals with microevolution occurring over a shorter time period, whereas divergent evolution deals with species evolution from their ancestors over a larger time period. Adaptive radiation was observed in finches of Galapagos and Hawaiian island. Galapagos Island is basically an archipelago consisting of a group of major and minor islands which is geographically isolated from mainland of South America and is inhabited by 15 different species of Darwin's finches belonging to tanager family (Losos and Mahler 2010). Each of these bird species evolved from a single common ancestor of mainland and then diverged in order to adapt to the different kinds of habitat, available food resources, and local conditions of the new island (Neige 2015). Through the forces of natural selection in action, genes that favored better dietary adaptation accumulated and lead to remarkable diversity in shape and sizes of beaks

**Divergent Evolution,**

**Fig. 1** Figure depicting formation of new species through adaptive radiation

D

of these birds. Species divergence increases with greater accumulation of structural differences. The major categories of Darwin's finches that diverged are ground finches, warbler finches and tree finches. In Fig. 1 the formation of new species through adaptive radiation has been depicted.

### Forelimbs of Mammals and Homologous Structures

An astounding example of divergent evolution is the forelimbs of mammals. In order to fill in the variety of niche available, mammals diversified from a recent ancestor by accumulating different adaptive traits which eventually led to speciation. This divergence (adaptive radiation) can be clearly seen in the various modifications of the forelimbs of different mammals like whale's fin, human arm, elephant's leg, and bat's wings (Weatherbee 2008). Although each of these structures is specialized for different function, the basic anatomy of forelimbs, that is, bone structure, is similar indicating they evolved from a recent common ancestor. Thus, divergent evolution might lead to formation of homologous structures as is in the case of forelimbs of mammals. Thus, homologous structures are organs or bones showing functional diversity but similar anatomical features indicating a shared common ancestry resulting from divergent evolution. In conclusion, greater accumulation of structural differences among related species indicates that species divergence has been in action for a longer time period.

### Other Common Examples of Divergent Evolution

- (a) Human and apes evolved from a common primate ancestor. Similarly, woolly mammoth and elephants have diverged from a common ancestor.
- (b) Divergent evolution is exemplified in the diversity of orchids with different adaptive traits.
- (c) Another example of homologous structure (resultant of divergent evolution) is observed in thorns of Bougainvillea and tendrils of cucurbits as both are modifications of axillary bud.
- (d) Kit fox (*Vulpes macrotis*) adapted to desert environment and arctic fox (*Vulpes lagopus*) adapted to cold climates diverged from a recent common ancestor to adapt to their varying extreme habitats.

### Speciation

The most important and concluding consequence of divergent evolution is speciation (Schluter 2001). Figure 2 depicts the occurrence of speciation event through divergent evolution. Genesis of new and separate species as a result of the lineage splitting evolutionary process is speciation. Many environmental agents of differential (divergent) selection pressure acts upon the variations (source being mutation and genetic

**Divergent Evolution,**  
**Fig. 2** Divergent evolution  
 leading to speciation

recombination) present in the gene pool (Barton 2010) and might bring about major differences or accumulation of a number of minor differences in adaptive traits which would eventually lead to change in structure or phenotype. The aim behind all this work is survival, adapting to change and achieving reproductive success. When ecological basis of divergent selection leads to speciation then it is known as ecological speciation (Rundle and Nosil 2005). Ecological speciation is the development of gene flow barriers or reproductive isolation in response to divergent selection pressure (ecological in nature) like environmental differences, sexual selection, and species interaction. Although there are other ways or chance events like polyploidization, genetic drift, founder effect, hybridization, and bottleneck effect that could lead to speciation (Coyne and Allen Orr 1998). Sexually reproducing organisms undergo speciation due to development of reproductive barrier through evolutionary process which restricts gene flow between populations (Turelli et al. 2001). Thus, reproductive isolation (premating or postmating isolation) is the critical requirement for speciation in sexually reproducing organisms. Geographical isolation is contributory in diversification of populations leading to speciation.

Modes of speciation are commonly categorized by making use of geographical context that results in reproductive isolation (restricted gene flow) among populations (Mayr 1947). Thus, according to geographic classification, four

means of speciation are allopatric, sympatric, parapatric, and peripatric (Mayr 1947; Schluter 2001). For the speciation process to occur, there are certain prerequisites that need to be fulfilled and they are prezygotic isolation mechanism, source of divergence (including spatial divergence leading to geographical isolation), source of divergent (including disruptive) selection, transmission of divergent selection or evolutionary forces (genetic drift, mutation, natural, and sexual selection) on reproductive isolation traits and presence of variation in gene pool to increase isolation (Kirkpatrick and Ravigné 2002). These forces work in unison and lead to speciation. Pleiotropism (direct selection) and linkage disequilibrium (indirect selection) are two processes that are instrumental in transmission of divergent selection of ecological characteristics/traits to genes developing reproductive barriers (Kirkpatrick and Ravigné 2002). Speciation event is continuous and generally extends over many generations (Coyne and Allen Orr 1998). In the subsequent section, different modes of speciation have been discussed in detail.

### Allopatric Speciation

*Allopatric speciation* is the most familiar form of speciation. Allopatric speciation arises when restricted gene flow occurs among populations because of physical isolation generated due to geographical barrier. Thus, spatial separation or physical isolation triggers divergence and leads to

development of gene flow barriers. Until and unless reproductive capability is restored through certain selective forces, the isolated subpopulations will become more incompatible with time (Turelli et al. 2001). Geographical isolation or some kind of physical barrier between two subpopulations is mandatory for allopatric speciation to occur. Natural selection and genetic drift acts independently on each separated population thereby producing varied evolutionary outcomes. In isolated small population, genetic recombination leading to new combination of traits or random mutation gets fixed by chance. Natural selection acts distinctively on these differences and leads to evolution of subpopulation differently from parent population (Boddum 2008). This type of speciation emphasizes upon the importance of geographical isolation and ecological adaptation.

### Peripatric Speciation

*Peripatric speciation* is quite comparable to allopatric speciation. The only distinction is that it occurs when from a much larger population a very small subpopulation with smaller gene pool isolates which is more responsive to natural selection and genetic drift. This greater sensitivity of smaller population (smaller gene pool) to selective forces is known as Founder effect, which leads to rapid divergence and speciation (Lawson et al. 2015). Like allopatric speciation, physical isolation between founder peripheral population and parent population forms the basis of restricted gene flow in peripatric population. Due to the selective forces like genetic drift and natural selection, the isolated smaller population differs in allelic frequency from origin population. Further, spatial/geographical separation leads to accumulation of new additional genetic variations that might cause reproductive isolation between parent population and smaller founder population (Lawson et al. 2015). This may or may not lead to speciation.

### Sympatric Speciation

*Sympatric speciation* is the form of speciation in which gene flow is blocked due to intrinsic factors like nonrandom mating or chromosomal changes

(Boddum 2008). This form of speciation is most debated because it lacks any physical form of isolation. The steering force behind sympatric speciation is disruptive selection (Turelli et al. 2001). It occurs in cases where populations are within geographical reach of each other or share same habitat/environment and do not have extrinsic barrier to gene flow. Due to the reproductive barriers among individuals of a population, new species evolve within the geographical reach of parent population. In allopatric speciation, complete isolation is achieved, whereas in case of sympatric speciation continued gene flow might occur for generations even after populations separate or diverge (Schluter 2001).

### Parapatric Speciation

*Parapatric speciation* is rare and occurs when a small subpopulation starts diverging from its parent population when it enters an extreme different niche while remaining within its original habitat (Yamaguchi and Iwasa 2017). The subpopulation develops reproductive barrier because of intrinsic factors rather than geographical isolation and might lead to speciation. Since the diverging subpopulation is small (smaller gene pool) the selective forces (founder effect, genetic drift and natural selection) can also play pivotal role in speciation.

### Conclusion

Divergent evolution is a universal and complex process. A better understanding of divergent evolution can solve many questions pertaining to evolution of diverse life forms on Earth. Divergent evolution plays primary role in generating the diversity of species (biodiversity) through the process of speciation. Different species thrive in diverse habitats by adapting to them. Divergent evolution or selection confers adaptive ability to ancestral species to evolve in new/changing habitats and environment. This adaptability causes accumulation of diverging traits that makes them dissimilar from their ancestor and leads to speciation, the most important consequence of divergent evolution. Development of homologous structures is the most important manifestation of

divergent evolution. The development of homologous structure is the evidence that divergent evolution confers ability of ecological adaptation in varying environment to different species with same ancestor. Thus, divergent evolution is the key player in maintaining the biodiversity, structural, and functional integrity of ecosystem.

## Divided Attention

Walter T. Herbranson  
Whitman College, Walla Walla, WA, USA

## Synonyms

[Simultaneous attention](#)

## Definition

Attention is a fundamental cognitive process by which some inputs are selected for preferential processing. Divided attention specifically refers to situations in which two or more channels are attended simultaneously. The attended channels may be within the same or different sensory modalities. For example, a foraging bird might attend to a pile of seeds while simultaneously listening for the sound of approaching predators. While divided attention can be useful and can support a range of complex behaviors, it is often accompanied by a decrement in performance relative to selective attention, or focus on a single input.

## Introduction

Divided and selective attentions have been extensively studied by cognitive psychologists. For example, in dichotic listening tasks (e.g., Cherry 1953), participants are simultaneously played two

auditory messages and asked to monitor one or both. Participants can usually report the contents of one message, though accuracy is often impaired relative to when a single message is presented in isolation. More importantly, the contents of the other channel are significantly but not completely attenuated, with only major physical changes (such as changes in pitch or voice) and subjectively important messages (such as the listener's name or taboo words) being recognized. This has been dubbed the “cocktail party effect,” in reference to the challenge faced by a conversant in a crowded ballroom.

While dichotic listening tasks are among the most widely utilized, similar results have been obtained from parallel visual procedures (Neisser and Becklen 1975), indicating that divided attention is not a purely auditory phenomenon. The results of such experiments have had profound theoretical implications and led to popular characterizations of attention as a bottleneck or selective filter (Broadbent 1958) that reduces inputs to an amount that can be managed by a limited capacity working memory. Though there is still debate about the nature of this filter and whether it applies relatively early or late in processing, most theories agree that attention to multiple inputs results in relatively poorer performance.

The complexity of the natural world and the corresponding diversity and sensitivity of many animals' sensory systems would suggest that a similar attentional filter would be quite useful for many nonhuman animals. Consequently, there have been efforts to apply similar logic and methods to study divided attention in nonhuman animals.

## Methods of Studying Divided Attention in Nonhuman Animals

One of the most useful and direct procedures for studying divided attention uses a variation on the classic matching to sample task (e.g., Maki and Leith 1973). An animal is presented with a sample stimulus on a center response key, followed by two comparison stimuli on adjacent side keys. On single-element trials, the sample and comparison stimuli are all of the same type (e.g., all colors or

all line orientations), and a response to the comparison stimulus that matches the sample is reinforced. On compound trials, the sample features two element types (e.g., a color and a line orientation), while the comparison stimuli still consist of single elements. A response to the comparison stimulus that matches either of the elements present in the sample is reinforced. Because the matching comparison stimulus could feature either of the elements present in the sample, an animal must divide attention between both sample elements in order to support accurate responding. Typical results indicate that there is an accuracy cost to divided attention: matching to sample performance is worse on trials with compound samples than on trials with single element samples. This result is consistent with bottleneck theories of attention: dividing attention between elements results in fewer resources allocated to each and thus poorer performance.

Divided attention also factors into other cognitive processes of interest to comparative psychologists. Categorization, for example, allows an animal to respond to a range of category exemplars with the same appropriate response, as when a pigeon recognizes a never-before-seen hawk as a dangerous predator and executes the appropriate evasive action. Given that the members of many natural categories vary immensely, and multiple perceptual dimensions may be simultaneously and jointly diagnostic of category membership, successful categorization frequently requires divided attention. While the numerous mechanisms underlying categorization are still being clarified, researchers have specifically investigated the role of divided attention in categorization. Herbranson et al. (1999) created artificial categories that varied continuously on two dimensions. Individual exemplars were rectangles that varied in height and width, and the relevance of each dimension to category membership was varied across conditions. In some conditions, only one dimension (either height or width) was diagnostic of category membership, whereas the other varied randomly and was unrelated to category membership. In other conditions, both dimensions

were jointly diagnostic of category membership, and thus accurate categorization required attention to both dimensions. Pigeons' responses were mathematically analyzed to assess attention to the two stimulus dimensions. Results indicated that pigeons were capable of selectively attending to a single dimension or dividing attention between two dimensions, as demanded by the category structures in effect.

Another example of a cognitive process influenced by divided attention is visual search. Many animals can effectively scan their environment to identify specific targets based on visual features. Foragers, for example, use a specific searching image to spot prey at a rate greater than would be expected by their distribution alone (Tinbergen 1960). Cryptic prey in turn protect themselves by using natural camouflage that forces predators to search for a conjunction of features, rather than a single visual feature (e.g., a combination of shape and color, rather than shape or color by itself). Conjunction searches require that attention be divided between multiple visual features and consequently are more difficult than single-feature searches (Treisman 1986). Cook (1992) investigated this in the lab by presenting pigeons with texture displays on a video screen. Pigeons were trained to peck a small odd region of an otherwise uniform array of elements. On feature search trials, the odd region was differentiated by a single feature such as color (e.g., a small blue region among green elements) or shape (e.g., a small region of circles among squares). On conjunction search trials, the odd region was differentiated by a conjunction of color and shape (e.g., a small region of blue squares and green circles among green squares and blue circles). Conjunction searches required divided attention and resulted in lower accuracy than feature searches, though both were above chance. These visual search results further elaborate on the nature of divided attention by indicating that attention is not distributed exclusively across spatial locations. It can be divided among features within the same sensory modality and even in the same spatial location and yield the same pattern of results.

## Conclusion

Animals have a limited processing capacity, yet live in a world where many aspects of the environment may be simultaneously relevant. In such cases, the ability to divide attention across multiple channels can be useful. Nevertheless, divided attention usually comes at a cost and results in poorer performance relative to situations that utilize selective attention. This ability to divide attention supports many critical cognitive abilities, including but not limited to categorization and visual search.

[Division of Physiological and Comparative Psychology](#); [Society for Behavioral Neuroscience and Comparative Psychology](#)

Throughout its 76-year history, the mission of Division 6 of the American Psychological Association (APA) has been to promote research and education in physiological psychology, behavioral neuroscience, and comparative psychology. Other goals are to support communication and coordination between scientists, both within and beyond the Division, and to build psychology as a science more broadly. Since its inception, scholars identifying as animal psychologists, behavioral neuroscientists, comparative psychologists, or physiological psychologists have affiliated with Division 6, recognizing several common characteristics of these subfields. Division 6 members focus on the biology of behavior – either directly through experiments on the neural and physiological systems that underlie and/or are influenced by behavior, or indirectly through the study of similarities and differences across species that might reflect biobehavioral adaptations. Accordingly, many Division 6 members have a common interest in nonhuman animals, whether in their own right or as models for human biopsychology.

Thus, physiological psychologists, behavioral neuroscientists, and comparative psychologists generally shared the need to advocate for animal research, with respect to policy, funding, regulation, acceptance, and representation in psychology broadly. Finally, scientists from the various subfields of psychology that affiliate with Division 6 are similar in their commitment to experimental psychology. This overlap with experimental psychology has resulted in a disrupted history for Division 6, the first five decades of which were described definitively by Professor Donald Dewsbury (1996).

But the history of Division 6 began before 1944 when the APA introduced its current divisional structure. The focus on biology and the use of animals toward empirical, academic, and basic-research oriented interests were evident in the early days of psychology as a science, and of the APA as the professional home for the science and practice of psychology. Among the early Presidents of the APA, there were pioneers in American physiological or comparative psychology such as Boring, Dashiell, Dunlap, Ladd, Lashley, McDougall, Sanford, Stone, Thorndike, Tolman, M. F. Washburn, Watson, Woodworth, and Yerkes. Thus, it is unsurprising that a Division of Physiological and Comparative Psychology (Division 6) was one of the 19 charter divisions of the APA upon the organization's move to a division-based model (Olson 1944). The division was relatively small, but strong by every other metric. As Dewsbury (1996) discussed, Wolfle (1948) rated APA divisions on various measures of size and commitment and found that only the Clinical Psychology division ranked as highly across measures as Division 6; although few in number, the division's members were very loyal in paying dues, active in convention programming, willing to be nominated for leadership positions, and responsive in voting. When the Division was formed, Clifford T. Morgan was its temporary chairperson and B. F. Skinner was its temporary Secretary. Donald G. Marquis was the first elected chairman, followed by Donald Lindsley. The office was changed to President in 1947, when Morgan was elected.

Between 1948 and 1963, APA Divisions 6 and 3 (the Division of Theoretical-Experimental Psychology) voluntarily merged (Dewsbury 1996; Peak 1948). Thus, there was no "Division of Physiological and Comparative Psychology" within APA, although members from these subdisciplines continued to participate in APA through Division 3 (which changed its name to the Division of Experimental Psychology in 1949). Led by Sydney Weinstein, however, APA members representing these specializations successfully petitioned to reestablish the Division of Physiological and Comparative Psychology as a new Division 6 in the APA (Dewsbury 1996; Newman 1962). In 1995, the division leadership elected to adopt a new moniker as the Division of Behavioral Neuroscience and Comparative Psychology (Dewsbury 1996). Twenty years later, in 2015, this name was adjusted into its current form as the Society for Behavioral Neuroscience and Comparative Psychology.

Table 1 lists the names of Presidents (including the chairmen, prior to 1947) and other officers of Division 6 throughout its history. Note that Division leadership has consistently reflected both the comparative psychology and the physiological psychology / behavioral neuroscience constituencies. Over the course of the division's history, its focus areas and leadership have drawn from the diversity of psychologists who use the study of animals as a critical component of their research programs. Some early leaders, such as Donald Lindsley, studied animals using neurophysiological methods to index reflexive behaviors and their neural bases (e.g., Lindsley et al. 1950). Others, such as Austin Riesen, studied perceptual learning and development of perceptual faculties using animals as a model species (e.g., Riesen 1947). Later leaders would build upon these trends, studying the neuronal embodiment of learned behaviors (e.g., Thompson and Spencer 1966) and the psychophysiology of arousal and startle responses (e.g., Weisbard and Graham 1971). The growing influence of cognitive sciences and comparative cognition in animal research can be seen in the research programs of more recent figures (e.g., Rumbaugh et al. 1987; Young and Wasserman 1997; Zentall et al. 1996).

<sup>a</sup>From 1950 to 2012, the secretary position was called “Secretary-Treasurer”

Among the efforts to support the fields it represents, Division 6 gives several awards annually. The current awards include recognition of the best paper published in each of the two APA journals most closely associated with the Division’s mission. The author or authors of an outstanding paper published in the *Journal of Comparative Psychology* are recognized each year with the “Frank A. Beach Comparative Psychology Award.” The author(s) of the best paper published each year in the journal *Behavioral Neuroscience* receives the “D. G. Marquis Behavioral Neuroscience Award.” Both of these awards are selected by the editorial boards of the respective journals. Additionally, the Division annually recognizes a scholar who has provided significant theoretical and empirical advances to these subfields with the “Donald O. Hebb Distinguished Scientific Contributions Award.” The “Brenda A. Milner Award” honors an author for an outstanding paper in the field of behavioral neuroscience or comparative psychology, and the “Clifford T. Morgan Distinguished Service Award” recognizes continuing exceptional service contributions to the Division. An “Early Career Investigator Award” is also conferred each year. These honors

and recognitions are announced at the annual APA convention, in which Division 6 regularly provides a strong program of science presentations and posters.

Despite this legacy of scholarship and leadership, Division 6 has long occupied a precarious position in the APA. Always a small group, the proportion of the total APA membership affiliated with Division 6 has declined steadily since it reemerged from Division 3. Dewsbury (1996) traced these membership trends through 1995, and those declines have continued to the present writing. Some of this trajectory is to be expected for any division that has been steadfast in its experimental and academic focus as the APA has become increasingly applied, clinical and political. But more structural issues are also likely to be in play. Since the late 1980s, the actual count of Division 6 members has fallen annually (from 806 members in 1986 to 405 in 2017, the most recent year for which data are available). Few indicators of future growth are apparent, with the demographic profile of Division 6 suggesting loyal retention of the division’s previous generation of members until death, but there is little evidence of attracting a new generation of

psychologists to the society (e.g., 73% of Division 6 members were aged 60 or older in 2017, with only 26% identified as female, and only 5% identified with a specific race or ethnicity other than white). Division 3 (the Society for Experimental Psychology and Cognitive Science) and some other divisions are experiencing these same trends. One might wonder whether this reflects a general decline in the subdisciplines that comprise Division 6. Psychologists have eulogized comparative psychology since at least the early 1970s (e.g., Lockard 1971; see also Abramson 2015; Galef 1987), to mixed reviews (e.g., Adler and Tobach 1971; Boice 1971); however, there are other signs that comparative psychology – particularly comparative cognition – is alive and growing. For example, the number of publications on “comparative psychology” or “comparative cognition” since 2000 is more than double the number from the previous 20 years, reflecting in part the increase in outlets for such work. In any case, certainly no claim can be made for the general demise of behavioral neuroscience. Together with cognitive neuroscience, social neuroscience, and clinical neuropsychology, these areas of scholarship are on the ascend. Specialty professional associations such as the Comparative Cognition Society, the Psychonomic Society, and particularly the Society for Neuroscience appear to be healthy and growing. Rather, the Division 6 membership trends discussed here appear to reflect ongoing challenges of attracting scholars from these subdisciplines to the APA. Its new identity as the Society for Behavioral Neuroscience and Comparative Psychology – affiliated as a division within APA but open also to members who choose not to join that larger organization – may determine what future role Division 6 plays in the subfields of psychology that it endeavors to promote.

all levels in biological systems, from cooperative associations of organelles in some eukaryote cells and microbes, to associations of specialized cells in simple animals (e.g., sponges), varied organs in complex unitary organisms, and specialized individuals in animal societies (Crespi 2001; Simpson 2012). Division of labor is thought to be one of the principal factors underlying the major evolutionary transition from solitary to social living, and key to the spectacular success of highly social organisms such as the social insects (Hölldobler and Wilson 1990; Wilson 1971).

Division of labor in social organisms can be considered an emergent group-level property of local interactions at the individual level and arises from variation among, and interactions between, the individuals comprising the group, without top-down control. In some cases, individuals may specialize predominantly on certain tasks because the propensity to perform different tasks differs among individuals. In other cases, individuals may constantly shift between tasks as a fluid solution to ever-changing group requirements, without necessarily specializing on any particular task (Robinson et al. 2009).

## Division of Labor

Adam L Cronin

Tokyo Metropolitan University, Tokyo, Japan

### Definition

The partitioning of tasks among individuals in a group, such that some individuals focus on one task while other individuals focus on another.

### Introduction

Economists have long recognized that dividing tasks among cooperating individuals can lead to improved efficiency, as this allows individuals to specialize on particular tasks while also reducing the costs of switching between tasks (Smith 1776). Division of labor is also widespread at

## Reproductive and Nonreproductive Division of Labor

The most fundamental form of division of labor is the skewed distribution of reproduction among members of a group: some individuals specialize in reproduction while others undertake nonreproductive tasks. In social insects, reproductive skew can be extreme, with colonies comprising a single reproductive queen and tens of thousands of nonreproductive workers. In cooperatively breeding mammals and birds, reproduction is typically monopolized by a breeding pair, aided by one or more “helpers” who perform a range of nonbreeding tasks. Division of labor is also found in microorganisms: slime molds, for example, usually exist as free-living individual amoeboid cells, but can aggregate on starvation into multicellular slugs, which then develop into a fruiting body consisting of (reproductive) spore cells and (nonreproductive) stalk cells.

Division of labor can also exist among non-reproductive individuals. The effective functioning of an ant colony, for example, requires a wide range of different tasks to be performed. Leaf-cutting ants of the genus *Atta* possess one of the most complex systems of division of labor in insects, associated with the elaborate process of harvesting leaves to tend the fungus gardens on which they feed. In *Atta sexdens*, no less than 29 distinct tasks have been identified, and these are performed by workers with four distinct morphological castes (Wilson 1980).

### Flexibility in Division of Labor

Division of labor can arise facultatively among undifferentiated individuals. In such cases, the role assumed by any given individual may change with context during that individual's lifetime. Cooperatively breeding vertebrates, for example, are typically totipotent (capable of all tasks) but choose social life over independence because of the benefits of social living and/or the costs of solitary life. As a member of a cooperatively breeding group, they may switch between dominant (breeder) and subordinate (helper) roles depending on various physical and socio-ecological factors. Similarly, many facultatively social wasps form dominance hierarchies maintained by aggression or other criteria such as relative age. Subordinate individuals perform foraging tasks while the dominant individual monopolizes reproduction, though once again these roles may change over time.

Division of labor can also be obligate. In queens and workers in many social insects, for example, roles are highly specialized and associated with morphological castes. While these castes allow individuals to perform their assigned role with greater efficiency and efficacy, they also mean a loss of totipotency, and thus dictate that any given individual is only capable of a limited range of the tasks essential for survival. Social insect queens, for example, are often specialized to produce large numbers of eggs but are incapable of basic labor tasks. Workers on the other hand have in many cases lost the ability to mate and/or reproduce, and instead are adapted for performing

a wide range of labor tasks, making these two roles mutually and obligately interdependent. This is also true for individuals in colonial scyphozoans. These animals form colonies of differentiated zooids in which individuals are not only obligately mutually interdependent, but also permanently physically connected. In this sense, scyphozoans perhaps most closely resemble the division of labor among organs systems in unitary multicellular organisms.

### Mechanistic Basis of Division of Labor

A group comprising individuals which vary in their propensity to perform different tasks can self-organize into an effective cooperative unit. While many societies are comprised of highly related individuals, these are not clones, and factors such as multiple reproductive individuals and multiple mating can result in increased genetic diversity among members of the workforce, which can itself lead to higher group efficiency (Smith et al. 2008). Individuals also vary in a wide range of factors including age, condition, morphology, and experience. The combination of these factors defines the propensity of an individual to perform a particular task (Oster and Wilson 1978; Wilson 1971), and individuals having lower "response thresholds" for certain tasks are more likely to perform those tasks. For example, many insects change role as they age, typically moving from less-hazardous roles within the nest to external roles such as foraging.

The propensity for individuals to perform certain tasks is subject not only to internal state but also external signals, such as changes in group-level requirements or environmental conditions. While individual caste, age, or genotype may largely define which tasks a worker is likely to perform, individuals may also vary their roles depending on the activity of other individuals and the needs of the group. For example, inside workers in an ant colony are likely switch to external foraging roles if they are unable to obtain food after soliciting nestmates, as this is likely to indicate a general lack of food in the colony. Effective division of labor thus depends on both variation between individuals in the tasks they are

likely to perform and flexibility within individuals to effect responses to variable environments (Beshers and Fewell 2001).

## Definition

In the course of fertilization, when two sperms fertilize two mature ova due to multiple ovulation under the control of hypothalamo-pituitary-ovarian axis promoted by different physiological, genetic, and other environmental factors, including the use of advanced reproductive technologies to maximize reproductive success.

## Introduction

The word “twins” originates from old English: “*twi*” means two or “*twin*” means double. Twin babies are although less frequent but not rare in parallel with the single child. Dizygotic (DZ) or fraternal twins are produced from two different ova fertilized by two different sperms whereas monozygotic (MZ) or identical twins derive from a single ova dividing into two separate embryos. Conjoint twins are also identical but not separated. Compare to the prevalence of monozygotic twins which is almost constant, the prevalence of dizygotic twins varies over time across the different places in the world. In animal society, twins are also prevalent and diversified like as reported in 2016 in South Africa, the world first twin puppies of Irish Wolfhound named Cullen and Romulus were born as the identical twin. Armadillo is another example to give birth to monozygote. Callitrichines, or clawed New

World monkeys, always give birth to twins because they produce multiple ova in their reproductive cycle.

History and Background of Twin Studies

The history of twin studies began with Galton’s study (Galton 1876); thus, he is considered as the father of twin studies and also the founder of the eugenics movement. The term “eugenics” means “well-born” and was coined by him. Galton failed to explain the cause of observed behavioral similarities in twins. In 1905, the first twin study with psychological testing was published by E. L. Thorndike. He also stated the influence of nature and nurtured on mental abilities for twins. To answer the question of the important role of common environment and experience on the mental development, he reasoned that:

- a. Twins should be more alike with increasing age.
- b. Similarity of ordinary siblings not more than 4–5 years apart should resemble the similarity of twin pairs.
- c. If experience influences mental abilities, then twins should be more similar for abilities that require training compared to those less subject to training.

He disputed the fact of the effect of experience on mental illness.

In the mid-1920s, two kinds of twins, MZ and DZ were first recognized. In 1924, Herman W. Siemens from Germany first proposed that the role of genetic factors for diseases or traits can be compared by comparing identical to fraternal twins reared together, thus introducing the classic twin method. In 1934, Wilson questioned the environmental impact on twins. In the same year, Helmut von Bracken found that identical twins experienced a higher degree of attachment compared to fraternal twins. Rosanoff and colleagues (1938) conducted their studies on schizophrenia, criminality, and delinquency in twins to conclude the role of social factors in developing abusive attitudes.

Weinberg was a popularizer of the “differential method,” which uses a simple calculation to estimate the number of expected identical pairs in a given population of twins. He also created the first “morbidity tables” used in medical statistics, as well as an age-correction method subsequently used by several twin researchers. Germany also contributed to twin research immensely. In 1928, Hans Luxenburger published the first schizophrenia twin study followed by another study performed by Johannes Lange in 1929. The most unethical practices were performed during World War II by some German physicians notoriously labeled as “Nazi Medical Experiments.” During that time, the prisoners in the camp were experimented upon without their consent. The Auschwitz and Roman twins were infested with bacteria and other pathogens for genetic studies. Following this sad history of twin studies, several animal and clinical studies were performed throughout the decades.

Beside all these studies, the most well-known twin study was Minnesota Studies of Twin Reared Apart (MSTRA) conducted by Thomas Bouchard and his colleague between the year 1979 and 2000. In 1990, Buchard and his colleague reported the correlation of physical variable, IQ, and personality test scores in monozygotic twins reared apart (MZA) and reared together (MZT). In brief, the result was tabulated below.

| Features               | Correlation for MZA | Correlation for MZT |
|------------------------|---------------------|---------------------|
| IQ                     | 0.69 (48 pairs)     | 0.88 (40 pairs)     |
| Personality test score | 0.50                | 0.50                |

Based on the result in the context of psychology and sociobiology, the team of MSTRA concluded that this is because of strong genetic influence and the similarity in the score is not due to shared family environment. The study was published in Science in the year 1990 where they mentioned that monozygotic and dizygotic twins who were separated early in life and reared apart are a nature’s experimental beauty and also provide the ample and powerful opportunity to study the influence of environment and genetics on human characteristics.

## Importance of DZ Study

Despite some methodological and ethical issues, twin research continued beyond this unfortunate history due to several reasons, including due to failure of molecular approaches in describing psychiatric disorders, genetic theories for economic and political needs, and few important publications on twin research between 1961 and 1970 (as published by Jay Joseph in his book “The Gene Illusion” and “The Trouble with Twin Studies”).

Twin study is one of the most potent and valuable tools in genetics research to assess and analyze the importance and influence of genetic factors on phenotypic and trait variation in humans. Understanding which genes are responsible for natural twinning and to know how they control ovarian functions is critical for applications in female fertility and infertility.

## Epidemiology and Prevalence

During the seventeenth century, birth registration was recorded in church registries and was officially introduced in 1749 in Sweden and Finland (Erikson 1962). From statistics recorded therein, it was possible to calculate twinning rates (TR). The TR (number of twin maternities/1000 maternities) varies geographically across Europe/North Africa, Sub-Saharan Africa, and Asia. The highest TR is observed in sub-Saharan Africa (23/1000) and the lowest in Asia (5–6/1000, Bulmer 1970). Based on international variation in TR, Little classified it as low prevalence (2–7/1000, e.g., Hawaii, Japan, and Taiwan), intermediate prevalence (9–20/1000 North Africa, America, Asia, Oceania, and Europe), and high prevalence ( $\geq 20/1000$  Nigeria, Seychelles, Transvaal, Zimbabwe) TR countries. Among the high prevalence countries, Yoruba is reported as the highest prevalence of TR (33–66.5/1000) where 1 in every 12 families has twins (Nylander 1971, 1978). In 1900, TR decreased, and from 1970 onwards, it increased steadily in most countries (Imaizumi 1997). Such demographic variations arise due to several reasons, which can be the environmental, physiological, feeding habit, genetic, etc.

**Twinning Promoting Factors:** From the TR found all over the world, it has been documented that there is an increased TR in the last two decades. The contributing factor that promotes the TR includes the use of various fertility treatments like in vitro fertilization (IVF), intracytoplasmic sperm injection (ICSI), intrauterine insemination (IUI), and ovulation induction (OI).

## Factors Affecting Twinning Rate

Principal factors that affect the twinning rate are maternal age, parity, and genetic inheritance. Several factors contributing to alteration of twinning rate are:

- (A) Increased maternal age: for example, a four-fold increase in TR from age 15 to 35. Maternal age and parity are well correlated and increase the risk of dizygotic twins (Bulmer 1970).
- (B) Body type: for example, tall women ( $\geq 165$  cm) with high BMI ( $\geq 30$ ) are much more at risk (1.5–2 times) of giving birth to twins than women of small stature ( $\leq 155$ , Basso et al. 2004; Bortolus et al. 1999; Nylander 1981).
- (C) Smoking: Women who smoke are at higher risk of giving birth to twins compared to non-smokers (Parazzini et al. 1996).
- (D) Seasonal variation: Conception during summer and autumn are reported to contribute higher rates of DZ in several countries (Eriksson and Fellman 2000). The seasonal variation in day length causes the alteration in hormonal level, which may be the cause of multiple ovulations. Seasonal foods and food supply were considered as contributing factors for DZ (Eriksson and Fellman 2000).
- (E) Iatrogenic factors: Oral contraceptives and Folic acid also influence DZ (Li et al. 2003). Folic acid consumption during conception increases the risk of DZ (Vollset et al. 2005). Soon after stopping oral contraceptives, conception leads to increased risk of DZ (Rothman 1977). Although there are some contradictory findings regarding the

association between oral contraceptives and DZ, the overall pattern can be described as recovery from exogenous steroids causing an increase of FSH level temporarily via hypothalamo-pituitary-ovarian axis (HPO), which leads to multiple ovulations (Jernstrom et al. 1995).

- (F) Genetic factors: Because height is correlated with dizygote births as the first link of twinning with heredity, Weinberg (1901) reported that mothers, sisters, and daughters of the mother with twins had an increased risk of having twins and the percentage probabilities are 39, 95, and 30%, respectively. Despite the concept of the female line contribution in DZ as supported by other scientists strongly (Bulmer 1970; Wyshak and White 1965), Greulich (1934) reported the contribution of paternal hereditary factors in DZ also. Meullemens and colleagues (1996) reported an autosomal monogenic dominant model by analyzing pedigree of 1422 Dutch and Flemish families with DZ twins, which supports inheritance from both parents. Semen quality may influence DZ twinning (Askund et al. 2007).

births. Two hypotheses have been put forward to explain the twinning rate of humans.

- A. The insurance ova hypothesis: The hypothesis states that increased production of multiple ovarian follicles will increase the probability of survival and at least one of them being fertilized. Therefore, conceiving twins is the by-product of encouraging fertility (Anderson 1990).
- B. Natural selection hypothesis: This hypothesis consults the effect of environments that promote twins or singletons as the reproductive output.
  1. In an experiment conducted by Lumma and colleagues (1998) in the archipelago of Åland, Åboland, and the mainland of Finland, to their surprise, they found that enriched food source islands were inducing twinning frequency whereas, in the poorer mainland environment, singletons are preferred to maximize the reproductive success.
  2. Similarly, during World War II, the scarcity of foods provokes singleton births, and again in subsequent years, food enrichment encourages twin births (Bulmer 1970).

D

## Hypotheses

From the previous research, four hypotheses are developed.

1. Increase in multiple ovulation frequencies leading to an increase in the frequency of spontaneous DZ.
2. The concentration of FSH is above a certain threshold by extending the time or by increasing the number of responding antral follicle to FSH during follicle selection.
3. Women with a family history of multiple births are already predisposed to multiple ovulations.
4. Gene mutations affecting multiple ovulation rates are most likely from FSH pathway of synthesis, maturation, and release of the dominant follicle.

Although during pregnancy, complications are prevalent in producing twins rather than singleton

## Mechanism

Mechanism of controlling dizygotic twinning is a complex phenomenon and still obscure. Multiple ovulations due to improved nutrition and particular gene mutations are reported in animals. Increasing follicular recruitment was found in those mothers who give birth to twins (Martin et al. 1991b). There are mainly two ways by which the control mechanism works.

1. Hypothalamo-pituitary-ovarian axis is the complex regulatory network that controls the ovulation. Two important gonadotrophin hormones, follicle-stimulating hormone (FSH) and luteinizing hormone (LH), secreted from the pituitary alter the pattern of the menstrual cycle. In the characteristic pattern of the menstrual cycle, in the early phase, FSH concentration begins to increase and, in a feedback manner, the hormone secretes from growing

follicles, (Inhibin) inhibits hypothalamus and pituitary to secrete FSH – causing FSH levels to fall. Development of one dominant follicle takes place when the concentration of FSH exceeds the threshold level, and for multiple follicle developments, FSH (independent of LH pulse) is more, or FSH exceeds the threshold for too long.

2. Ovarian follicular control – Although this pathway responds to the external FSH and LH signals and ensures the oocyte development, two closely related growth factors expressed specifically in the oocyte, bone morphogenetic protein 15 (BMP15), and growth differentiation factor 9 (GDF9) play another major role (Shimasaki et al. 2004). These two factors bind to the receptor expressed on ovarian cells, which ensures oocyte growth and development.

## Genetic Variants and DZ

Apart from these two control mechanisms, genetic variants of FSH receptor (e.g., Thr307Ala and Asn680Ser), causing the increase in sensitivity towards FSH, contributes to variation in DZ (Ayman et al. 2000). The genetic variant's contribution to DZ is still contradictory (Montgomery et al. 2001). Bone morphogenetic protein receptor1B (BMPRI1B, Duffy et al. 2001) and methylenetetrahydrofolate reductase (MTHFR, Montgomery et al. 2003), Inhibin alpha (INHA, Montgomery et al. 2000) are also enlisted among those genes that play a role in DZ. Female carriers of Fragile-X syndrome (FRAXA) are also reported to have an increased risk of DZ (Kenneson and Warren 2001). Carriers of FMR1 permutation are also at risk of DZ (Welt et al. 2004). Substitution of C to T in PPRAG gene (encoding peroxisome proliferator-activated receptor (PPAR $\gamma$ )) is also associated with DZ (Busjahn et al. 2000).

## Sex of Twins

Because DZ is more common than MZ throughout the world, the question arises of the frequency

of same-sex (SS) DZ and opposite sex (OS) DZ. French statistician Jacques Bertillon (1874) first speculated that the  $DZ = 2OS \text{ twins} + MZ \text{ twins}$ . Later Weinberg (1901) formalized Bertillon data and proposed two assumptions known as Weinberg's differential rule (WDR). The WDR states that (a) probability of conception of the male and female fetus are equal ( $P = 0.5$ ). (b) The sexes of DZ twins are determined independently. So,  $DZ = \text{equal number of } (OS+SS)$ . But the ratio is slightly more towards boys (105:100). The Trivers Willard hypothesis pointed at some doubt with the second hypothesis of WDR and stated that parental conditions have an impact on sex ratios. According to this hypothesis, parents in enriched food and other physiological conditions give birth to males, and, in poor environmental and physiological conditions, to females. Similar effects for OS and SS have been observed; if conditions are good, both are male, but if conditions are poor, both are female (Trivers and Willard 1973). OS is considered evolutionarily and developmentally disadvantageous compared to SS; then, the WDR hypothesis of independent sex determination for DZ is violated, and SS will be produced more than OS.

## Chimerism

When an organism contains cells derived from more than one zygote, this is referred to as chimerism. Although chimerism is a rare event, monochorionic dizygote (MC/DZ) twin is a comparatively new area of research. Blood chimerism has been found commonly in MC/DZ. Monochorionic twin pregnancies have complications related to vascular anastomoses, which cause twin-twin transfusion syndrome. There are many such cases; for example, at birth, male recipient twins have two bloodlines, 30% 46XY and 70% 46XX, whereas female donors have 18% 46XY and 82% 46XX (Chen et al. 2013). No anomaly in reproductive growth has been reported except few cases like a girl having Down syndrome with blood chimerism (Bogdanova et al., 2010). She was a normal female with normal genitalia and fallopian

tubes, but aplasia in the uterus, which may be due to the Mullerian inhibiting substance (MIS).

## Conclusion

In the course of multiple ovulations, when two sperm fertilizes two ova, dizygotic twins are formed. The worldwide variation of twin frequency reflects that South African Yoruba people have a high probability of having twins. Several assisted reproductive technologies like IVF, ICSI, IUI, and OI contribute to increasing the frequency of DZ production. The enriched environment and different factors like folic acid consumption, smoking, high BMI, and increased maternal age favor the process of DZ. Because enriched food sources promote DZ, the natural selection hypothesis comes forward along with insurance ova hypothesis to increase the chance of fertilization. The search for mechanisms behind multiple ovulations establishes the hypothalamo-pituitary-ovarian axis. Several genes like GDF9 and BMP15 control the ovarian follicles. Other gene variants that contribute to the DZ processing are BMPR1B, MTHFR, INHA, FRAXA, and PPARG. Twin research continues in spite of ethical issues because of its potential impact on behavioral genetics, psychology, and different diseases.

Uttar Pradesh, India

## Definition

Deoxyribonucleic acid (DNA) is a polymer of nucleotides containing nitrogenous base, deoxy-ribose sugar, and phosphoric acid which stores and transmits genetic information.

## Introduction

DNA is a macromolecule that carries the genetic information for biological functions of living organisms. It is made up of two strands of polynucleotides coiled around each other to form a double helix. Nucleotides are the basic building blocks of nucleic acids formed of two components, nucleosides and phosphate groups, where phosphate group attaches to the 5' position of a nucleoside by ester linkage. Nucleosides are also composed of two elements, a five-membered pentose sugar and a nitrogenous base. Further, nucleotides join together by the formation of a second ester bond by reaction between the phosphate of one nucleotide and the 3' hydroxyl of another, thus generating a 5' to 3' phosphodiester bond between adjacent sugars; this process repeats indefinitely to give a long polynucleotide molecule. DNA has two such polynucleotide strands having free 5' hydroxyl group at one end and 3' hydroxyl group at another end in each strand. Therefore, each strand is having a polarity and directionality in opposite directions and known as antiparallel strands. Nitrogenous base in DNA is basically of two types – purines consisting of adenine (A) and guanine (G) and pyrimidines consisting of thymine (T) and cytosine (C) (Fig. 1).

**DNA, Fig. 1** Simplified structure of DNA

## DNA Structure

James Watson and Francis Crick (1953) identified the correct structure of DNA existing as a double helix on the basis of Chargaff's chemical data and Wilkin's and Franklin's X-ray diffraction data. The double helix model of DNA molecule further suggested the mechanism of transmission of genetic information. Watson and Crick proposed that DNA exist as right-handed double helix in the cells in which two polynucleotides are coiled around each other in spiral manner. These polynucleotide strands are held together by hydrogen bonds between bases of opposing strands and thereby maintain their helical configuration. The base pairs are stacked between the two chains perpendicular to the axis of molecule. This base pairing is specific as adenine always joins with thymine by double hydrogen bond and guanine binds with cytosine by triple hydrogen bond. Thus, all the base pairs consist of one purine and one pyrimidine and these two strands of the DNA

are complementary. The complementarity of the two strands of the double helix makes DNA suitable to store and transmit genetic information from one generation to another.

The base pairs in DNA are stacked about 3.4 Å apart, with 10.4 base pairs per turn of the double helix. The angle between the two adjacent residues in the same chain is 360. The distance of the phosphorus atom from the fiber axis is 10 Å. The twisting of two strands around each other forms double helix with a minor groove (~12 Å across) and a major groove (~12 Å across). This double helix structure is right handed as the turns run clockwise along the helical axis.

## DNA Forms

DNA exist in three conformations, B-DNA, A-DNA, and Z-DNA (Wang et al. 1979). The Watson-Crick double helix structure is called B-DNA. DNA remains in the B-DNA conformation

under physiological conditions (aqueous solution having low salt concentrations). B-DNA appears to have an average of 10.4 nucleotide pairs per turn. Further, the structure of DNA molecule change as a function of their environmental conditions and interaction with its surrounding molecules. Under high salt concentration (state of dehydration), DNA exists in A-DNA conformation. It is also a right-handed helix like B-DNA but with 11 nucleotide pairs per turn. It is a shorter, thicker double helix with a diameter of 2.3 nm. DNA does not exist in this conformation in vivo. However, DNA-RNA heteroduplexes exist in this conformation in vivo. Certain DNA sequences exist in a left-handed double helical form known as Z-DNA. It is also found in double helices which are GC rich and contain alternate purine and pyrimidine rings. It differs from A and B conformations in having 12 base pairs per turn, with a diameter of 1.8 nm and a single deep groove. The function of Z-DNA in living cell is still unclear.

## DNA Organization

Functional DNA molecules in living cells display a very high level of organization, i.e., supercoiling (Gilbert and Allan 2014). Supercoils are introduced into a DNA molecule when strands are cleaved and the complementary strands at one end are rotated or twisted around each other with the other end held fixed in space and thus not allowed to spin the DNA molecule. The DNA is maintained in a tightly coiled conformation as a consequence of supercoiling. The DNA molecules of almost all organisms exhibit negative supercoiling in vivo which helps in several biological functions. Supercoil in DNA molecules is further maintained by enzymes that play essential roles in DNA replication and other processes.

## Conclusion

DNA usually exists as a right-handed double helix with the two strands held together by hydrogen bonds between the complementary bases in which

adenine is paired with thymine and guanine is paired with cytosine. The complementarity of the two strands of a double helix makes DNA unique to store and transmit genetic information. The two strands of a DNA double helix have opposite chemical polarity as they are antiparallel. Further, the functional DNA molecules in cells are negatively supercoiled.

## DNA Marker

Hendrik de Buhr  
ETH Zurich, Zurich, Switzerland

### Synonyms

[Genetic marker](#); [Molecular marker](#)

### Definition

DNA, genetic, or molecular markers are known as clearly distinguishable DNA, gene or molecular sequences on specific locations on chromosomes.

### Introduction

Mutations or alterations in genomic loci (positions on chromosome) lead evolutionary to polymorphisms (genetic variations) between species and individuals which can nowadays be quickly examined and compared. DNA markers are employed for various purposes. They are mainly used for genealogical DNA testing, evolutionary taxonomy (phylogenetics), and genetic traits underlying (inherited) diseases. Through identification of known and clearly distinguishable DNA, gene, or molecular sequences it is possible to create a physical and/or linkage map and allow for differentiation of traits and identity. In addition, the allelic status (variant form of a gene) can be detected (mono-, bi-, or polyallelic).

Historically the first employed DNA markers were allozymes (allelic variant form of enzymes coded from the same locus) and mitochondrial DNA (mtDNA).

### Types

DNA marker can vary in length from very short sequences like single nucleotide polymorphisms (SNPs) to long fragments like minisatellites

(repetitive DNA with certain motifs). In general, they can be divided into molecular and biochemical markers. Molecular markers are variations in the DNA like deletions, insertions, inversions, and/or duplications. Biochemical markers use variations in the gene products (e.g., proteins). Markers are either dominant/recessive or codominant regarding their mode of inheritance. Codominant markers are more valuable because they are able to distinguish between homo- and heterozygotic patterns (Liu and Cordes 2004). All the DNA markers naturally have their pros and contras. Therefore, it is important to know what exactly the underlying objective for the use of which specific DNA marker is.

### Examples of Application

DNA markers allow for a variety of applications. One of their main functions is to allow for the identification of the relationship between inherited diseases and their underlying genetic causes.

For example, a genome-wide association study (GWAS) is an epidemiologic survey of common genetic variants within a given population. The aim is to search for single nucleotide polymorphisms (SNPs) within individuals that are correlated with a trait or disease. SNPs are variations in the DNA common to the population, as opposed to mutations, which are changes in the DNA away from the normal allele, and are only found in rare instances. Therefore, a phenotype-first approach is normally employed where the genetic sequences of diseased (called case) and healthy (called control) patients are compared, by scanning using a SNP array for sequence variations. So far almost 150 million SNPs have been identified (Sherry et al. 2001). Alleles (variants) more frequent in cases are seen to be more associated with a disease (Manolio 2010; Pearson and Manolio 2008). While polymorphisms within a population have been identified as increasing risk for a disease, the studies are merely association studies, and do not provide functional evidence towards disease development or progression.

Another example emerged during the examination of the transmissible agent of canine transmissible venereal tumor (CTVT). Two hypotheses competed against each other where one postulated that virus-like particles induced cell transformation versus allograft infection (transplantation of cells from a nonidentical donor) as the second hypothesis. The employment of genetic markers identified that the tumor cells themselves evolved into the transmissible parasite (natural transmission) and further were able to elucidate the age of the tumor and its phylogenetics through its breed of origin (Murgia et al. 2006).

Conclusion

DNA markers are powerful tools with a broad variety of purposes and serve either to examine known molecular sequences or to determine unknown fragments close to them. Depending on its application it is possible to choose from a broad range of different marker (see Table 1) which have emerged more and more recently with the technical progression. Therefore, nowadays it is possible to exactly analyze the molecular

identity, differences and origins of various species and between individuals.

DNA Pooling

Hendrik de Buhr  
ETH Zurich, Zurich, Switzerland

Definition

DNA pooling is an approach where DNA from multiple individuals is pooled into a single DNA mixture for library preparation and sequencing.

## Introduction

DNA pooling methods are subdivided into two categories. The first category comprises the non-overlapping pooling methods where each individual is put in only one pool and each pool has a limited number of individuals. Whereas the overlapping pooling methods insert each individual in multiple pools to recover the genotype of each of them. DNA pooling decreases the costs for genotyping in large-scale association studies and was first introduced by Erlich et al. (2009).

## Application

The cost of sequencing the genotype of single individuals has strongly decreased in recent years due to high-throughput sequencing (HTS) technologies. For example, a genome-wide association study (GWAS) is an epidemiologic survey of common genetic variants within a given population. The aim is to search for single nucleotide polymorphisms (SNPs) within individuals that are correlated with a trait or disease. SNPs are variations in the DNA common to the population, as opposed to mutations, which are changes in the DNA away from the normal allele, and are only found in rare instances. Therefore, a phenotype-first approach is normally employed where the genetic sequences of diseased (called case) and healthy (called control) patients are compared, by scanning using a SNP array for sequence variations. So far almost 150 million SNPs have been identified (Sherry et al. 2001). Alleles (variants) more frequent in cases are seen to be more associated with a disease (Manolio 2010; Pearson and Manolio 2008). The identification of putative susceptibility genes for various diseases (e.g., diabetes, schizophrenia, Crohn's disease) are examples of the functionality of this approach (Wasson 2007). While polymorphisms within a population have been identified as increasing risk for a disease, the studies are merely association studies and do not provide functional evidence toward disease development or progression. In order to perform GWAS and detect common and rare SNPs, it is necessary to collect large cohorts of

cases. Whole genome sequencing in general would be the method of choice but is still very expensive for large cohorts. The costs for sequencing come down to two parts. The first is the most labor-intensive and the so-called library preparation cost consisting of the DNA sample preparation. The second part is the sequencing itself as per-base cost. Due to technological advances the costs for sequencing are becoming less over time, whereas the library preparation costs are quite stable. Multifold studies employed overlapping DNA pools to determine rare casual SNPs with high accuracy. The problem in these cases is the assumption that all individuals show the same abundance level in the pools which might lead to falsified associations. This could be eradicated by a probabilistic modelling of individual abundance levels (Hormozdiari et al. 2012). Nevertheless, this procedure is the main application for large-scale association studies usually without the addition of probabilistic modeling.

## Conclusion

DNA pooling is a cost reducing approach for the sequencing of large cohorts of individuals in order to identify common and rare SNPs among individuals. The SNPs are associated with traits or diseases and therefore could be used for detection and prevention. In addition, advances in technology make this method more and more affordable for broad application.

## DNA Repair Hypothesis

Dhirendra Kumar Sharma  
Molecular Biology Division, Bhabha Atomic  
Research Centre, Mumbai, India

### Synonyms

[Evolution of sex](#); [Sexual adaption](#)

### Definition

To repair the genetic material is the primary function of sex, and this is known as “DNA repair hypothesis.”

### Introduction

Sexual reproduction is necessary for our evolution. In sexual reproduction, progeny is similar to their parents, not the same due to genetic variation in each generation. The genetic variation facilitates adaptation. Progeny after sexual reproduction is young and genetically different from their parent. This young progeny went through different sequential gene regulation (upregulation/downregulation), i.e., on or off of different gene

during different development phases. This young progeny does not reflect the age of their parent because it is from germ cells, not from somatic cells (aged cells) (Bernstein 1979) (Gensler et al. 1987). Lack of aging in germ cells is because of cell arrest ( $G_0$  phase) and mitotic recombination. To repair the genetic material is the primary function of sex, and this is known as “repair hypothesis.”

### Hypothesis

In biological system (DNA or RNA), noise reflects damage or mutation in the genome, and this is a serious problem. Sexual reproduction is selected in evolution to avoid mutation and damage in DNA/RNA. Before sexual reproduction and during gametogenesis, germ cells undergo meiosis (cell division) and in this process recombination of the gene by homologous recombination. This homologous recombination leads to the selection of genes, and during this recombination process, a mutation leads to a new allele in populations (Felsenstein 1974).

If you compare damage versus mutation, the damage is any alteration in genetic material (DNA/RNA) which can be recognized by enzymes and repaired. DNA damage is caused by any high-energy radiation, free radicles, addition or deletion of any functioning group on nucleotides, single- or double-strand break, thymine dimer caused by UV cross-linking, and others. This damage blocks replication and leads to cell arrest, then the repair protein tries to repair it, and it is repaired, and then division continues; otherwise, cell leads to apoptosis. These damages are not inherited to the next generation because these are lethal to the cell and not replicable (Bernstein 1979), whereas in mutation are changes in the coding sequence of DNA/RNA. Due to a change in coding sequence either a change in protein expression level increases or decreases, truncated protein which in non-functional and this leads to reduce or sometimes rarely increase fitness. These are mutations not detected by enzymes, so, with the change in the genetic material, therefore, they are replicable and transfer to the next generation. Low frequency of

mutation is required for evolution to acquire new adaptive information (Bernstein et al. 1987). Mutation in one copy of genomes is masked up by homologous copy which is known as complementation. If the mutation has negative effect, the individual gets eliminated from the population by natural selection because of less fit.

There are two fundamental benefits of sexual reproduction explained by repair hypothesis. First is the recombination and to understand we need some background. Recombination is the major repair pathway in the diploid organism. Each diploid cell has two copy of genome: one is paternal, and the other is maternal. Entire genome segmented in chromosomes and each chromosome have coding as well as the noncoding region. This noncoding region helps in the regulation of the gene. In the territory of the chromosome defined in the nucleus, during meiosis I, the homologous sets of chromosome come closer and align parallel to each other. After alignment, the recombination process starts, and there is a huge shuffling of genes or chromosomal regions. This recombination process is required to the selection of genes from two different individuals (parents), and that is why the progeny has characters from both parents (H. Bernstein et al. 1985). Recombination proves the repair hypothesis in germ cells. The second fundamental is outcrossing which is required for the complementation of mutation that occurred in the homologous chromosome. This outcross is also required to increase genetic diversity and reduce the probability of carrying any hereditary disease or genetic abnormality. Finally, the two fundamental pillars of sexual reproduction are recombination and outcross which help in the repair of genetic material and complementation of genetic disease (Kodric-Brown and Brown 1987).

## Conclusion

Sexual reproductions are selected during the evolution because it gives similar progeny, not the identical one, and it also gives enough time to repair DNA. If the reproduction is by the asexual method, then a mutation carried to next generation never gets repaired in the same or next generation.

While in case of sexual reproduction, these mutations may be repaired by the recombination process (meiosis). The other copy that repairs the mutated copy is the same cell, i.e., the maternal copy repaired by paternal or vice versa. If a mutation is given fitness to population, then this has to accumulate in the population which is done by outcross and it distributed into the population.

## Domain Specificity

Sang Ah Lee  
Department of Bio and Brain Engineering,  
Korea Advanced Institute of Science and  
Technology, Daejeon, South Korea

### Introduction

A domain-specific view of the mind describes cognition as consisting of mental computations specialized in handling selective inputs in order to achieve a particular purpose. Such a “mental toolkit”-like characterization of our minds is contrasted with theories of domain generality that claim that all-purpose learning mechanisms can sufficiently account for all cognitive abilities. Related to the view of domain specificity is the theory of modularity (Fodor 1983). Mental modules invoke the idea of domain specificity and take it one step further by committing to their innateness, neural specificity, automaticity, and encapsulation (i.e., independence from other modules).

Perhaps the most intuitive way of illustrating domain specificity is through examples of instinctive behavior in both humans and nonhuman animals. Instincts are often broadly defined as automatic, fixed behaviors and responses shared by all members of a particular species (i.e., genetically predetermined). We think of behaviors such as a spider’s ability to spin a web, a bird of paradise’s mating dance, a koala’s selective consumption of eucalyptus leaves, and a human baby’s laugh or cry as being instinctive. Each of these behaviors is innate (not learned through experience), elicited only in particular situations, involves a particular set of behaviors, and serves a particular purpose for the organism. Although instincts were initially thought to be independent from cognition, this distinction is gradually being blurred as scientists gain more insight into the cognitive underpinnings of animal behavior, on one hand, and the instinctive nature of human cognition, on the other.

Domain-specific theories provide biologically and psychologically consistent explanations of

functionally specialized mental processes that have been selected over the course of evolution. However, they are often criticized for the degree of “hard-wiring” they invoke and the apparent lack of emphasis they put on experience and plasticity.

## Core Cognitive Domains

Developmental psychologists coined the term *core knowledge* to refer to the domain-specific cognitive mechanisms that humans innately possess from infancy that are evolutionarily ancient and shared with other species (Kinzler and Spelke 2007). Four main domains of core knowledge have been characterized in detail thus far: objects, space, numerosity, and social agents. Language is sometimes referred to as another core domain, but its origins are still debated (Tomasello 2008).

*Objects.* The core domain of objects concerns macroscopic, inanimate objects and their physical behavior. Young animals and newborn human infants treat objects as solid and spatiotemporally continuous, expecting object parts that move together to be connected (Spelke 2003). They track such individual objects through space but are limited in the number of objects that they can track at once. This set size limit of about four, which can also be found in adult subjects in tasks of multiple object-tracking, has led researchers to link the core domain of objects with the mid-level object attention system in adults (Feigenson et al. 2004). In infants, this system allows babies (both human and nonhuman) to organize the perceptual world into bounded wholes and to learn to associate them with various features, concepts, and behaviors.

*Animate agents.* There are entities in the world that are not subject to constraints on their physical characteristics (as in the domain of objects) – animate agents. We are endowed with a predisposition to look at and attend to other animate beings who are potential social partners, competitors, predators, or prey. There are several specific physical and behavioral properties associated with agents, including face-like inverted

triangular arrangements of features, presence of eyes, contingent behavior, intentionality, causality, and self-propelled movement (Kinzler and Spelke 2007). Such properties are thought to guide our attention to our social companions, as well as potential threats, and to guide our learning to be able to expertly discriminate each individual from another. Studies of neural specificity in mechanisms underlying the conceptual organization of animate beings and face processing have made major contributions to the scientific discussion surrounding domain specificity (see next section).

*Number.* The ability to track a small number of individuals can be said to be a part of the core object system, but a different system is responsible for the ability to estimate numbers of elements in a set and perform mathematical operations over them. The core system of number is often referred to as an approximate magnitude representation system with properties such as scalar variability (i.e., larger numbers have larger errors) and ratio-based distinguishability (Feigenson et al. 2004). It allows us to represent, compare, and remember numerical quantities of sets of objects regardless of the individual identity (e.g., quantity of berries on a bush or number of people in a rival tribe) or modality of input (e.g., either through seeing, touching, or hearing). The accuracy and precision of the core number system has been linked to mathematical competence in both children and adults (Bugden et al. 2016).

*Space.* The first three core domains concerned representations of entities in space. But we also have a core representation of space itself, which allows us to mentally map our surrounding environment and navigate through it. Decades of research in both animal models and humans have established a detailed understanding of the neural basis of the cognitive map in the hippocampus. Core spatial representations consist of directional and distance relationships among locations and are particularly attuned to 3D environmental boundary structures (Lee 2017). The strong influence of boundary geometry on behavior (and the brain) has been well-documented across both humans and nonhuman animals, and researchers have debated for decades over the

existence of a “geometric module” underlying spatial navigation.

## Neural Specificity

Humans have known for many years that damaging certain parts of the brain can often result in the selective loss of specific mental functions. For instance, most of us have heard about memory deficits following damage to the medial temporal lobe, or the loss of verbal abilities after damaging fronto-temporal cortical regions such as Broca’s area. Some of the most powerful evidence for domain specificity in studies of human cognition come from studies of brain-damaged patients with selective conceptual category deficits. For example, damage to a particular area of the left temporal lobe can impair a person’s ability to recognize or name animate beings (e.g., animals) but not inanimate objects (e.g., artifacts) (Caramazza and Shelton 1998). This selective deficit has been shown to occur at the conceptual level, independently of the perceptual modality of presentation (e.g., both visual and auditory).

The advent of neuroimaging techniques in the past few decades has made it possible for cognitive neuroscientists to spatially localize and analyze human brain activity in response to particular types of stimuli and tasks. For instance, visual processing of faces, objects, and scenes has been correlated with activity in areas such as the OFA/FFA (occipital/fusiform face area), LOC (lateral occipital complex), and OPA/PPA (occipital/parahippocampal place area), respectively (Grill-Spector et al. 2001). Such findings have generally been taken as evidence in favor of a domain-specific organization of concepts in the brain.

## Domain Specificity and Learning

A common mischaracterization of domain specificity is that it is a deterministic view of human mental capacity. Although it is true that the roots of domain specificity lie in the evolutionary origins of mental adaptations, by no means does it

undermine the importance of learning and experience. In fact, core representations can be said to direct our attention and intention to ward specific things in specific situations so that we can *learn* the right information for the right purposes from the earliest days of development.

Taking face recognition as an example, it is possible that domain-specific mechanisms can be a result of a combination of innate predisposition and experience. An example of such a case is in the origins of face preference and face recognition (Kanwisher 2010). Although infants prefer faces over non-faces from birth, they become experts at discriminating faces of the social category (e.g., race, species) that they are perceptually exposed to over the course of development. Furthermore, the FFA has been shown to activate, in some cases, for non-face stimuli that people learn to expertly differentiate (Gauthier et al. 2000). Therefore, if both behavioral and cortical specialization in facial recognition could be a result of experience, it follows that some domain-specific processes may not *necessarily* be innate. Further research in cognitive neuroscience will lead to clearer insight as to the origins of domain specificity in behavior and the brain.

## Conclusion

Just like other organ systems of the body, the brain has adapted to perform specific functions. Domain-specific mechanisms provide animals with the basic tendencies, biases, and cognitive abilities that allow them to interpret relevant sensory input and respond to it quickly and precisely. Domain-general processes, then, may add associative data to the existing structure that allows individuals to modulate their behavior in accord with their experience. In particular, humans start out equipped with the basic domain-specific processes that we share with other animals, we overcome their limitations across development to create abstract, symbolic human knowledge systems that can be flexibly applied across conceptual domains (Carey and Spelke 1994). How this happens is a major

challenge for the fields of developmental and cognitive science to address in the future.

## Domestication Hypothesis

Joy Vincent  
Oakland University, Rochester, MI, USA

## Definition

The domestication hypothesis was developed by Hare et al. (2002) in an effort to explain the seemingly innate ability for dogs to follow human social cues to find food. The hypothesis predicts that domestic dogs should be better at using human social cues in goal-oriented tasks than wolves because domestication selected for the ability to read human communicative cues. Therefore, experience should not affect performance on tasks requiring such communication. Since its inception, the domestication hypothesis has stood against a series of alternative hypotheses and continues to be one of the most prevalent and widely held hypotheses on the topic.

## Introduction

It has long been observed that there is a unique connection between domestic dogs and humans. “Man’s best friend” is often applied to describe

the close bond between the two species. This bond is accentuated by dogs' ability to seemingly understand human communication cues – notably, their ability to understand pointing (Udell et al. 2010). This ability has long fascinated scientists, as few animals are able to understand human gestures. There have been numerous hypotheses presented in attempts to explain how and why this ability evolved in dogs. One of the most generative hypotheses was presented by Hare et al. (2002) and is known as the “Domestication Hypothesis.” Generally, it asserts that, during the process of domestication, humans specifically selected for traits that enabled dogs to perform tasks requiring communication with humans, which allowed dogs to evolve the capacity to understand and react to human-produced directional cues (i.e., pointing) in goal-oriented contexts (i.e., foraging) that their non-domesticated counterparts do not possess.

More specifically, the hypothesis can be broken down into two main tenets. The first is that “dogs should be more skillful than wolves” (and other non-domesticated species) on human-based, goal-oriented tasks; the second is that “variations in experience with humans should not affect the performance of either species” in using human communication cues (Hare et al. 2002, p. 1634). In their flagship paper introducing the domestication hypothesis, Hare and colleagues outline the results of a series of studies they conducted. There were three main takeaways from the results.

First, Hare et al. (2002) compared domestic dogs and chimpanzees on their ability to use human social cues to find hidden food. They found that, while domestic dogs were easily able to find the hidden food, chimpanzees were less skillful at applying the social cues. Similarly, they also found that domestic dogs performed better than wolves on a similar task (Hare et al. 2002). These results lend credence to the first tenet of the domestication hypothesis that dogs should be more skillful than their non-domesticated counterparts. They also studied the performance of dog puppies at a variety of ages to explore whether developmental stage or ontogeny affected their performance. In line with the hypothesis, they found that the puppies' ability to use human social

cues did not vary with their age, but rather it was consistent at a high level across ages. This finding supports the second tenet of the hypothesis that variations in experience should not affect performance. Each of these findings, taken together, supports the main tenets of the domestication hypothesis. However, since its conception, there have been a series of alternative hypotheses presented to explain deviations from these tenets.

## Domestication

To fully understand the domestication hypothesis, it is important to first outline domestication. Hare and Tomasello (2005) broadly suggested that it was the result of convergent evolution of complex social skills in dogs and humans in response to social pressures that allow dogs to understand human gestures. Other researchers have alternatively suggested that this capacity in domestic dogs comes from their acceptance of humans as social companions (Hare et al. 2002; Hare and Tomasello 2005; Udell et al. 2010). Both propositions agree with the overarching process by which domestication came about: artificial selection.

Artificial selection is the process through which dogs are selectively bred for certain traits. Through this process, individuals with the desired traits are mated with one another, artificially inflating the incidence of those traits. Notably, individuals that were more attuned to human communicative cues were bred, progressively producing individuals that excelled at reading human cues, as the genes controlling that behavior pattern has been magnified over generations (Agnetta et al. 2000). Hare and Tomasello (2005) postulated that artificially selecting for individuals with the desired temperament and social skills presented the necessary pressures for human-like social intelligence to develop. They paralleled this with a type of self-domestication in modern human societies, wherein selection for a more tolerant and cooperative nature resulted in the evolution of a “tamer” human temperament.

Communication is crucial to effective cohabitation and cooperation, which is why dogs that

were able to use human-produced social cues were at a selective advantage. Not only did it increase the likelihood of their genes carrying on to the next generation through selective breeding, but it also created a new niche for them in humans' lives (Hare et al. 2002; Hare and Tomasello 2005). This increased interaction between dogs and humans allowed for enculturation, which is a process by which opportunities for individuals to communicate and interact with humans enhance their cognitive skills, particularly on social tasks involving humans (Call and Tomasello 1996). In other words, through the process of artificial selection, domestic dogs evolved enhanced communication abilities that were specifically tailored to human cues.

### Alternative Hypotheses

The studies conducted by Hare et al. (2002) provide evidence in support of their hypothesis, but it is not these results that provide the most compelling argument in favor of the domestication hypothesis. Instead, it is the rebuttals of alternative hypotheses that lend the most credence to this hypothesis. There have been a number of alternative hypotheses proposed both before and after the domestication hypothesis that attempt to explain the unique link between domestic dogs and humans.

The canine cooperation hypothesis was proposed by Range and Viranyi (2013) and is predicated on the idea that dogs' ability to use human social cues is a form of dog-human cooperation; and since wolves have demonstrated the ability to cooperate with one another, that constitutes the basis for dogs evolving the ability to cooperate with humans. Through the process of artificial selection, these traits increased over the course of many generations, resulting in domestic dogs having high levels of social attentiveness and tolerance. The most notable issue with this hypothesis is that, if the only trait that is necessary to use human communicative cues is the ability to cooperate, then wolves should be able to use human-directed cues in the absence of experience with humans. As outlined above, wolves were

able to perform comparably only following extensive socialization; they do not innately demonstrate the ability to follow human gestures or gazes (Hare et al. 2010).

Another hypothesis that draws on behaviors seen in wolves to describe those in domestic dogs is the canine generalization hypothesis, which suggests that non-domesticated canids should perform at least as well as dogs on social tasks, as they do on nonsocial tasks (Frank and Frank 1982). The logic underlying this hypothesis is based on the general flexibility of canids in the types of social information that they are able to use (Hare et al. 2002). Lampe et al. (2017) found that wolves that had been extensively socialized by humans were able to follow both a human's point and gaze to a food reward with similar proficiency to dogs. Whereas the researchers acknowledged that the success of the wolves in their study does not eliminate the possibility that domestic dogs evolved a predisposition to learn about human social cues faster, they argued that the wolves' performance was sufficient to disprove the first tenet of the domestication hypothesis.

In a similar study, Udell and colleagues (2008) found that wolves actually outperformed domestic dogs in an object choice task, while using human pointing cues. Hare et al. (2010) issued a rebuttal of the results, reanalyzing the data from Udell and colleagues (2008). The reanalysis showed that the initial results were artifacts of the wolves being more willing to participate in trials. Thus, when looking at participation and correct choice separately, the wolves and dogs performed similarly. It is possible to then say that, regardless of the reanalysis, wolves still performed comparably to dogs, which supports the canid generalization hypothesis. But Hare et al. (2010) emphasized that these wolves had also been extensively socialized, whereas dogs are able to use human-based cues independent of their experience with humans. This suggests that the canid generalization hypothesis is based more on individual ontogeny, rather than evolution of certain abilities through the process of domestication.

The same group of researchers presented their alternative to the domestication hypothesis – the

Two Stage Hypothesis (Udell et al. 2010). It posits that the ability for canids to understand human social cues depends on two ontogenetic experiences: interaction with humans during a sensitive period and learning ability that is not restricted to a specific developmental phase. It presents itself as a more parsimonious explanation for dogs' abilities to use human social cues and provides four interesting critiques for the domestication hypothesis. First, they call into question the presupposition of the development of some advanced cognitive ability in domestic dogs, pointing to Coppinger and Coppinger's (2001) results that domestic dogs have smaller brains than wolves, as potential evidence to the contrary. Second, they draw on their earlier results, showing that wolves were able to perform comparably to dogs after extensive socialization, suggesting that the ability is not the result of some evolutionary adaptation, but rather ontogenetic in its origins (Udell et al. 2008). Third, they argue that it is unlikely that dogs could have an innate ability to exploit human communicative skills because they are different species. Finally, they point to Scott and Fuller's (1965) results that outlined the critical role of experience in the development of social interactions in canids.

In addition to the above critiques of the domestication hypothesis, the Two Stage Hypothesis has seemingly been able to side step the counterargument that dogs as young as 4 months old have demonstrated the capacity to use human-based cues. Udell and colleagues (2010) pointed out that domestication is associated with closeness to humans, a relationship that is not addressed by the domestication hypothesis, and thus the Two Stage Hypothesis predicts that experience with humans will positively correlate with object-choice task performance (Udell et al. 2010). They further argued that, even at 4 months old, it is incredibly unlikely that puppies have had no conditioning to human gestures prior to testing, even if unintentional. They also highlighted the difference in development speed between domestic dog and wolves; domestic dogs develop slower, which allows for the sensitive period for socialization to be extended, whereas wolves have a relatively fast

development and a small socialization period. They argue that, even if both dogs and wolves were socialized with humans for the same amount of time at the same age, by virtue of their different development speeds, domestic dogs would have spent more time socializing with humans during that sensitive period. The Two Stage Hypothesis thus suggests that both domestic dogs and their wild counterparts are equipped with the necessary cognitive abilities to understand human-directed cues and any observed differences are the result of different critical periods and exposure to humans.

The framework of the Two Stage Hypothesis, in conjunction with its critiques of the domestication hypothesis, brings awareness to some of the shortcomings of the domestication hypothesis. Additionally, it seems to have found an alternative conclusion for the earlier results with the 4-month-old puppies (Agnetta et al. 2000). However, an often-overlooked element of Agnetta et al.' (2000) study showed that the puppies were readily able to use a variety of novel human-directed cues to find food. This ability to spontaneously use novel cues conflicts with any purely ontogenetic hypotheses, as it does not rely on previous experience.

## Conclusion

The domestication hypothesis (Hare et al. 2002) is one of many explanations for how dogs developed the ability to follow human social cues to find food. While the hypothesis is not without detractors, it has withstood scrutiny over the years. The domestication hypothesis is an evolutionary explanation for why dogs can follow gestures. It predicts both that dogs should perform better on human-guided, goal-oriented tasks compared to non-domesticated species and that experience should not affect performance. In a follow-up, Hare and Tomasello (2005) asserted that dogs and humans experienced the convergent evolution of complex social skills due to similar social pressures. It is through this process that both human and dog temperaments became tamer and better suited for interspecific cooperation. There is still

much to learn about the domestication process and how it yielded the unique behaviors we see today.

## Domestication Syndrome

Jennifer K. Link

SUNY New Paltz, New Paltz, NY, USA

Domesticated animals are so intertwined with the lives of modern humans, it is often difficult to imagine how we lived without them; for much of our evolutionary history, however, we did just that. Not until roughly 12,000 years ago did early humans discover agriculture and change everything. They learned how to domesticate certain edible plants, as well as certain animals, like cows, sheep, pigs, goats, and horses (Barker 2009). Of course, these livestock and food animals were not the first to find themselves cohabitating with humans, that title goes to the dogs. Perhaps the way dogs changed and molded into the loving pet they are inspired early humans to try to replicate that in other animals. But dogs were the first.

Though still uncertain, some put dog domestication as far back as 40,000 years ago (Hare and Woods 2013). One thing is for sure, however: Dogs were fully domesticated by 14,000 years ago. By this time they had even reached a point in the household where they were honored enough to be buried their owners (Janssens et al. 2018). Dogs were the prototypical domesticated animals, and rightfully earned their place as “Man’s Best Friend,” but what lead up to this transition from wolf to dog?

The story that is often told is of a group of early humans stealing some wolf cubs and raising them as their own, then slowly but surely breeding them over generations until they became the dogs we see today (Clutton-Brock 1977). As oft repeated as it may be, this explanation doesn’t account for the animosity that has always existed between humans and dogs, nor does it address how widespread dogs became. Instead, ancient wolves likely began by eating the trash of early humans. They likely got closer and closer to human camps, their offspring getting more and more tolerant of humans, then one day they were allowed into the camp. This began the domestication of wolves

into dogs, and it may be happening to even more species around the world now (Hare and Woods 2013).

Scholars have long observed some key similarities between those animals that humans have domesticated. These animals often had floppier ears, spotted coats, curlier tails, shorter snouts, and reached sexual maturity younger. Some scientists tried to argue that these things had been intentionally bred for; perhaps splotchy coats were easier to see in a field, or that domesticated animals needed to be able to give birth to more offspring in less time (Tchernov and Horwitz 1991). They posited that, in many ways, domesticated animals were bred to be dumber than their wild counterparts; that these animals had smaller brains because there was no need for them to be intelligent (Diamond 2002). Scientists up to this point were looking at domestication as a collection of specific traits bred by humans for specific purposes, but no one wanted to look at the whole picture. This is where Russian scientist Dmitry Belyaev comes in.

Belyaev began his research with the belief that there was yet more to know about how domestication happens. The best way, he thought, to find out how domestication truly works would simply be to domesticate an animal from scratch. Thus began one of the most influential and prolific studies on domestication in history (Dugatkin and Trut 2017).

Starting under Soviet Rule in 1958, Belyaev began his research under the guise of simply trying to breed better foxes for the fur trade. At the time, genetics research was all but outlawed, with many geneticists (including Belyaev's older brother) being executed for their research (Dugatkin and Trut 2017).

In order to create this experiment, Belyaev, with the help of young aspiring scientist Lyudmila Trut, selectively bred generations of foxes. In order to determine which foxes to breed, Trut would simply reach into the fox enclosure with her heavily gloved hand. Those foxes who were least fearful or aggressive towards the keepers' hand were bred with each other. Astonishingly, after only three generations of following this same procedure with all the fox kits, selectively bred

foxes began to show slightly more docile, tolerant traits than their freely bred counterparts (Trut 1999).

In just a few short generations, and over the course of only 40 years, the foxes who had been bred simply for tolerance towards humans were remarkably different. Beyond just being a bit friendlier towards humans, these new foxes began exhibiting more dog-like traits: Wagging tails, shorter snouts, and spotted coats (Dugatkin and Trut 2017). Where randomly bred foxes growled or cowered at the back of their enclosures, these new foxes ran to the front and begged for pets (Dugatkin and Trut 2017; Hare and Woods 2013; Trut 1999).

Past researchers had simply looked at each of the symptoms of domestication separately (Diamond 2002; Tchernov and Horwitz 1991), but this new experiment provided clear evidence that those symptoms were byproducts of simply breeding for tolerance towards humans. This discovery was coined *Domestication Syndrome*, which describes a set of traits that arise in an animal when that animal becomes domesticated. These are traits we see in many domestic animals, they include: floppier or reduced ears, shorter muzzles, smaller teeth, smaller brain, more frequent fertility, higher levels of serotonin, and, of course, higher levels of docility (Hare and Woods 2020).

It must be noted here as well that while the case of these Siberian foxes is the most longitudinal and famous, other scientists have sought to replicate the findings with other animals. One researcher sought to domesticate chickens in just the same way that Belyaev domesticated his foxes. In order to do this, Red Jungle fowl (the species from which all chicken are said to derive) were collected in a group and bred exclusively for tolerance (i.e., lack of fear) towards humans. In just eight generations, the Red Jungle fowl had increased hatch weight, increased growth, higher metabolism, higher food intake, higher serotonin, higher boldness, more dominance, smaller brains and other organs, and increased plumage (Agnvall et al. 2017). Though these changes are not identical to those seen by Belyaev, the similarities are hard to dismiss, particularly when two species

with such incredible differences at start are compared.

There is still very much to learn from those doing research on domestication and on the effects that it could have and is having on the animals who most often interact with humans. In pursuit of that knowledge, Trut has taken over since Belyaev's death in 1985, and she and her team continue to publish articles and books on the important work being done there (Dugatkin and Trut 2017; Trut 1999).

## Dominance

Daiani Kochhann  
Center of Agrarian and Biological Sciences,  
State University of the Acaraú Valley,  
Sobral, Ceará, Brazil

## Synonyms

Peck order

## Definition

Dominance is an attribute of the pattern of repeated agonistic interactions between two individuals, characterized by a consistent outcome in favor of the same dyad member and a default yielding response of its opponent rather than escalation. The status of the consistent winner is dominant and the loser is subordinate (Drews 1993).

## Introduction

The term dominance was first introduced by Thorleif Schjelderup-Ebbe in 1922, when he observed the behavior of domestic hens, describing their agonistic behavior (mainly pecking) and the formation of a dominant hierarchy. Schjelderup-Ebbe describes dominance in order of pecks: if A pecks at B and B never or seldom reciprocates, then A is dominant to B and B is subordinate to A.

Since that, the study and our understanding of dominance in social animals had increased a lot. Dominance among individuals in social groups is typically defined in terms of agonistic behavior,

with offensive or aggressive attack characterizing the dominant, and defensive or submissive behavior, the subordinate (Blanchard et al. 1993). To characterize a true dominance relationship, the subordinate should have a response other than escalation of the aggressive behavior toward the dominant.

Drews (1993) reviewed the literature about dominance, and proposed the definition as a relationship between individual animals, established by aggression and submission, and, dominance does not exist until one of the individual defers. Most of the time, the dominant individual has a priority access to multiple resources, such as food, mates, and territory. It is important to point that, although some authors observed a heritability in dominance, relating it to personality traits (David et al. 2011), most authors agreed that dominance is a relative measure and not an absolute property of animal (Drews 1993), being, highly context dependent.

The dominance relationship is first established with fighting and agonistic behavior. However, for maintenance of the relationship, submissive and avoidance behavior, as well as displays, is normally the most common behavior. This will normally reduce aggression (see below). Individual recognition is not a necessary condition to produce the behavioral pattern of dominance (Drews 1993).

## Function

There are two points of views about the function of dominance in social animals. First one, dominance have the function of reducing aggression and potential awareness in agonistic relationship, as well as the cost related to agonistic interactions. Reduction in aggression is normally observable in natural and modeling studies, which could be due to an internal mechanism (e.g., Pagel and Dawkins 1997) or due to a spatial reorganization and an expanding distance among individuals (Hemelrijk 2000). The second point of view states that the main function of dominance is to portioning resources, determining which individual will have a priority to access them. As dominance

predicts the individual that will have priority in this access, individuals will seize all the opportunity to reach it (e.g., Robinson et al. 2011).

## Measurement

To determine the dominance relationship, the outcome in encounters between individuals in a period of observations should be observed. The most simple and straightforward way is:

- A is dominant to B if A wins more encounters from B than B from A
- A and B are equidominant if A and B have an equal number of wins and losses
- If no encounters have been observed, their relationship is unknown (De Vries 1998)

An important observation is that not all types of aggressive/agonistic behavior are suitable for determining the dominance relationship, and, the suitable behavior must vary among species. However, as a rule, submissive behavior, which occurs when one animal recognizes another as the dominant, is a clearer indication of the dominance relationship rather than aggressive behavior (De Vries 1998; Van Dierendonck et al. 1995).

## Conclusion

Dominance is a relationship between individual animals, established by aggression and submission, and is only considered true when one of the individuals defers, which reduces the cost of aggressive interactions. Most of the time, dominant individual has a priority access to multiple resources, such as food, mates, and territory.

## Dominance Hierarchy

Daiani Kochhann

Center of Agrarian and Biological Sciences, State University of the Acaraú Valley, Sobral, Ceará, Brazil

## Synonyms

[Pecking order](#); [Rank order](#)

## Definition

Social organization in which animals interact most of the time with aggressive or submissive behaviors, leading to the creation of a rank system.

## Introduction

Dominance hierarchies were first cited by Thorleif Schjelderup-Ebbe in 1922, when he described the social organization of domestic chickens. The so-called pecking order describes the order in which individuals have access to food. This order was maintained by aggressive interactions, mainly pecking, in which the chicken that gives pecking to another one was called dominant and was never pecked by others. The dominant also has more access to food. The chicken that was pecked was called subordinate.

## Function

The emergence of dominance hierarchies in social animals is very common in nature and has the function to reduce costs and risks on injury during resource (mainly food, territory, or mates) acquisition and defense. In an ultimate view, dominance hierarchies are supposed to increase fitness of all individuals involved in this social organization, mainly the dominant. Rank in the hierarchy influences behavior, physiology, health, and ability to mate.

## Hierarchy Properties

The most basic property of hierarchies is stability. It occurs when one animal in a pair consistently delivers all or at least most of their aggressive acts, and the other one performs all or most of the submissive acts over a period of time (Chase et al. 2003).

Another desired property of dominance hierarchies is transitivity. This means that among three animals, A, B, and C, if A dominates B, and B dominates C, then A dominates C (Appleby 1983).

## Types of Hierarchy

Dominance hierarchies are generally divided in two types: linear and nonlinear hierarchy.

A linear dominance is achieved when (a) there is any unknown or undefined relationship, for every dyad A and B in the group, either A dominates B or B dominates A, and (b) the dominance order is completely transitive (de Vries 1995). A nonlinear dominance hierarchy will happen if (a) there is at least one unknown or not defined relationship and (b) there is at least one circular relationship (e.g., A dominates B, B dominates C, and C dominates A) (Appleby 1983).

## How Dominance Hierarchy Is Set Up and Maintained

There are two main hypotheses to explain how linear hierarchies are set up and maintained: they are predetermined by differences in the attributes of animals, or they are produced by the dynamics of social interaction.

The first hypothesis are also called the “prior attribute hypothesis” (Chase et al. 2002). It states that the social linear hierarchy is explained by another linear rank in an attribute that is indicative of their dominance ability (Drews 1993). For example, the larger animal takes the highest position in the hierarchy, the second larger takes the next position, and so on. Attributes that are related to dominance ability can vary depending on study species, relying on physical, physiological, and behavioral characteristics.

The second hypothesis is that social interactions among members of the groups per se generate the hierarchies (Chase 1982). This is called the “social dynamics” hypothesis (Chase et al. 2002). The social dynamics that can generate hierarchies are (a) the so-called winner and loser effects, in which individuals that win one contest have a higher probability to win later ones, and individuals that lose one contest have a greater probability to lose the next one, and (b) the “bystander,” when individuals observe others encounters and adjust their behavior according with what they are seeing, learning with it.

## Conclusion

Dominance hierarchy emerges in social animals to organize priority of access to limiting resources. The dominance order is maintained by aggressive and submissive acts, and the rank order could be determined by physical attributes or social dynamics within the group.

## Donald Griffin

Patrick Drumm  
Arts and Sciences Division, Ohio University  
Lancaster, Lancaster, OH, USA

## Introduction

If you start with his first scientific publication as a Harvard freshman, Donald Griffin spent nearly seven decades doing scientific work. Over the course of his career, he accomplished two things that few scientists achieve in their lifetimes (Gross 2009). He discovered a previously unknown natural phenomenon that he named echolocation. Later in life, he accomplished something greater than that. He changed the way we understand the minds of nonhuman beings. He did neither of these things alone, but his intellectual prowess and unflagging dedication to mustering evidence convinced many of us, including some of the skeptics that inevitably raise objections as science progresses.

## Early Life

Born in Southampton on Long Island in 1915, Donald Griffin was an only child (Griffin 1998). His family moved to the countryside near Scarsdale, New York, then, after his father's retirement for health reasons, to Barnstable, Massachusetts. Griffin's early education combined

stints of home schooling and attending nearby private schools. His uncle, a Harvard comparative physiologist who helped found the Woods Hole Oceanographic Institution, stirred his curiosity about biology. Young Griffin became a trapper and before long was studying the skins of his prey by reading scientific journals when monthly orthodontic appointments permitted post-treatment stopoffs at Boston's Museum of Natural History (Griffin 1998; Gross 2009). At age 17, a visit to a private bird research station on Cape Cod taught him about banding birds to track their migrations. Soon he was catching and banding little brown bats for the same purpose. An investigation of their homing abilities after displacement led to his first publication (Griffin 1934). By that time he had begun his first year at Harvard.

## Education and Early Career Accomplishments

As an undergraduate, Griffin was a B student. His precollege background drew him into a biology-centered curriculum, but he reluctantly took E. G. Boring's introductory psychology course to fulfill a requirement (Griffin 1998). We can only wonder whether psychology à la Boring planted a seed about cognition that would take many years to sprout. Nevertheless, the arrival of Karl Lashley at Harvard in 1935 with a joint appointment in psychology and biology allowed Griffin to pursue his real interest – animal behavior.

Despite an overall second-rate academic start, Griffin's interest in bat behavior soon paid off handsomely. Having familiarized himself with the scientific literature on bats, including Lazzaro Spallanzani's eighteenth century report on experimentally blinded bats, Griffin identified an unresolved question. No one had fully explained bats' remarkable ability to sightlessly navigate. Speculation that they might sense high-frequency sounds provided a direction to pursue, but investigating that question required specialized equipment. Fortunately, Harvard physics professor, George Washington Pierce, had the necessary instruments (Griffin 1980; Griffin 1998; Gross 2009) and readily agreed to assist. Pierce's background in

top-secret sonar research for the US Navy uniquely qualified him as a collaborator. Pierce and Griffin (1938) demonstrated that bats indeed vocalized high above the range of human hearing, which is about 20,000 cycles per second (i.e., 20 kHz). However, they cautiously refrained from concluding that bats' ultrasonic calls served a spatial orientation function.

With Lashley's support, Griffin entered Harvard's biology graduate program. There he met Robert Galambos, a fellow graduate student, who was measuring the hearing of guinea pigs with cochlear electrode implants. When Galambos tested Griffin's bats using Pierce's ultrasound generator, the bats' cochleae responded up to 98,000 cycles per second (i.e., 98 kHz), at the upper limit of Pierce's equipment. In short order, the two graduate students published findings, controversial at the time, that bats heard their own reflected ultrasonic vocalizations to dodge wires hanging from the ceiling of an experimental room (Griffin and Galambos 1941). Galambos based his dissertation on the bat research, but the topic of Griffin's dissertation was bird homing. Later, Griffin (1944) invented the term echolocation when others documented its existence in humans and secret wartime technology based on reflected energy waves became public knowledge.

The timing of Griffin's doctoral degree roughly coincided with the entry of the United States into World War II. In 1942, he began war-related post-doctoral research in Harvard's Psychoacoustic Laboratory under the supervision of S. S. Stevens, a founder of modern psychophysics and the inventor of the scales of measurement we now use to determine appropriate statistical tests. In Stevens's lab Griffin worked to improve the clarity of voice telecommunications in noisy military environments, but his stature as a bat expert presently involved him in one of the most unusual episodes of wartime research ever to be declassified.

A secret weapon development program, eventually dubbed Project X-Ray but more commonly known as the "bat bomb," began with Griffin's input (Couffer 1992; Gross 2009). In 1942, the National Defense Research Committee (NDRC) asked Griffin to evaluate a proposal submitted by a Pennsylvania dental surgeon, Lytle S. Adams, who knew Eleanor Roosevelt. Adams had seen

millions of bats take wing at dusk from Carlsbad Caverns just before he heard about Pearl Harbor on his car radio. Outraged by the sneak attack, Adams drafted a proposal to use bats in retaliation against the Japanese. It made its way to the NDRC with White House approval. The plan entailed airborne release of thousands of bats equipped with small incendiary explosives timed to ignite after the bats took roost in the wood-frame buildings of Japanese cities. The subsequent conflagration would cripple the Japanese homeland. Griffin reversed his initial favorable assessment of the plan's feasibility after determining that bats could not bear the weight of the incendiary payloads. Nevertheless, the military proceeded to try to develop the project until abandoning it in 1944.

After the war, Griffin joined Cornell University's zoology faculty but returned to Harvard in 1953, eventually becoming chair of the zoology department (Gross 2009). During this time, he either collaborated with or inspired other researchers to refine the research on bat echolocation, including its neurophysiological basis (Gross 2009). His long-standing interest in bird navigation inspired several methodological innovations to study it, including the use of aircraft, high-altitude balloons, and radar. Gross (2009, p. 256) summarized Griffin's postwar endeavors as contributions to "...the discovery of other 'new animal senses' such as infrared vision in snakes, infrasonic signals in elephants, and orientation and discrimination in electric fish." Griffin also invited to America the European ethologist, Karl von Frisch, who had decoded the sophisticated dance language of honeybees. Motivated by skepticism, Griffin replicated and reported von Frisch's findings in the foreword of the eminent ethologist's English translation (von Frisch 1950). These accomplishments merely highlight Griffin's trajectory along a successful, albeit traditional, academic career. He did change his institutional affiliation once more, moving to Rockefeller University in 1965.

## Later Career

It was at Rockefeller University that he broke with the orthodoxy that then dominated the

science of animal behavior. In retrospect, Griffin's heresy seems inevitable. By the 1970s, a new zeitgeist in psychological science had emerged. European ethology had earned the respect of American psychology (Dewsbury 1984) and its founders, von Frisch, Lorenz, and Tinbergen, were awarded a Nobel Prize in 1973. The cognitive revolution was well underway, displacing behaviorist agnosticism regarding mental events, at least in humans. Against such a backdrop, Griffin (1976) proposed a parallel revolution that opened nonhuman cognition and awareness to scientific investigation.

Predictably, Griffin's proposal was attacked by skeptics (Gould 2004), but the times were indeed changing, and Griffin persevered in the face of adversity. He published a seminal article in the respected journal, *Behavioral and Brain Sciences* (Griffin 1978), which also publishes scholarly responses. Some of those responses were favorable. His subsequent books (Griffin 1984, 1992) advanced the cognitive ethology paradigm shift, and a body of research under this new paradigm grew. He also clearly enjoyed the controversy he set off (Griffin 1998).

Griffin retired to emeritus status at Rockefeller University in 1986 but remained an active scholar. Research with a variety of species ranging from bats to bees to beavers occupied his time as an associate of zoology at Harvard's Concord Field Station. His second wife, Jocelyn, who, according to Gould (2004), may have compelled him to seriously consider animal cognition, preceded him in death in 1998. Griffin died at home in Lexington, Massachusetts, on November 7, 2003. His death coincided with the acceptance of a manuscript reviewing the most recent evidence of consciousness in nonhumans (Griffin and Speck 2004).

## Donald O. Hebb

Richard E. Brown  
Department of Psychology and Neuroscience,  
Dalhousie University, Halifax, NS, Canada

## Introduction: The Education of Donald Olding Hebb

Donald Olding Hebb was born in Chester, Nova Scotia, Canada, on 22 July 1904, the first of four children. Both of his parents were physicians; his mother was the third woman to receive her MD from Dalhousie University (1896). Donald was taught at home by his mother until he entered the Chester School in the second grade. He stayed at this small rural school until he completed the eleventh grade and then finished high school at the Halifax County Academy in Halifax, Nova Scotia. He entered Dalhousie University in 1921

and majored in English and Philosophy. He was exposed to Psychology in two classes: Philosophy 1, which used William James's *Textbook of Psychology*, and Philosophy 9, which used Langfield and Allport's *Elementary Laboratory Course in Psychology* as textbooks. After graduating in 1925, he obtained a teaching certificate from the Provincial Normal School in Truro, Nova Scotia, and taught at his old school in Chester for a year until he moved to Montreal (Hebb 1980). Hebb was teaching at Verdun High School in Montreal when he met Professor W. D. Tait, the head of the Psychology Department at McGill, and attended Dr. Tait's night school class in psychology. From 1928 to 1930, he was a part-time MA student in Psychology at McGill under the supervision of Professor Chester Kellogg.

During the 1930–1931 school year, Hebb was bedridden with tuberculosis of the hip, which left him with a permanent limp. He convalesced at his father's home in Dartmouth, Nova Scotia, where he studied Sherrington's *Integrative activity of the nervous system* and Pavlov's *Conditioned reflexes*, and wrote a theoretical MA thesis which contains his first thoughts on the nature of synaptic activity during conditioning (Brown and Milner 2003). After the completion of his MA, Hebb began to work on his PhD at McGill, studying Pavlovian conditioning in the laboratory of Professor Boris P. Babkin, a former student of Pavlov. But he became disillusioned with Pavlovian conditioning procedures and his graduate studies at McGill and decided to complete his PhD under the supervision of Karl S. Lashley at the University of Chicago (Dewsbury 2002). Only a year after Hebb arrived in Chicago, however, Lashley moved to Harvard University and Hebb completed his PhD thesis at Harvard on the visual abilities of rats reared in the dark.

## **Hebb's Research Interests and Major Contributions to the Study of Animal Cognition and Behavior**

### **Human Neuropsychology and Intelligence**

Following his PhD, Hebb was appointed as a research fellow at the Montreal Neurological

Institute (MNI), under the supervision of Wilder Penfield. He administered psychological tests to patients who had temporal lobe and frontal lobe surgery (Hebb and Penfield 1940). Hebb's experience in testing patients at the MNI led him to develop a theory about the nature of intelligence and how it should be tested. With professor N. W. Morton of McGill University, Hebb developed two new tests: the verbal adult comprehension test and the nonverbal picture anomaly test. Hebb had also observed that lesions of different brain areas produced different cognitive impairments, and he developed the theory that intelligence was not unitary but a complex phenomenon, with multiple components that were differently affected by brain damage. He suggested that the different components of intelligence should be tested using specific neurological tests and came to believe that the age at which brain injury occurred was important in determining its effects on intelligence. He concluded that intelligence had two components, a fixed or innate component and a variable component that could be influenced by environmental experience, and he called these Intelligence A and Intelligence B (Hebb 1942). Cattell later renamed these as fluid and crystallized intelligence (Brown 2016). In 1939, Hebb became a lecturer in Experimental Psychology at Queen's University in Kingston, Ontario, and published his work on the effects of brain lesions at different ages and a review of frontal lobe function. He also designed a variable path maze and this Hebb–Williams maze has since been used in a number of studies of learning in animals and humans.

### **Primate Research**

In 1942, Hebb became a research associate with Lashley at the Yale Primate Laboratories at Orange Park, Florida. During this time, Hebb completed a number of studies on emotionality in chimpanzees and related these findings to human emotionality (Hebb 1947). In addition he continued his work on the development of rat intelligence. To determine the effects of early experience on learning, Hebb reared rats as pets at home and showed that enriched experience during development resulted in improved maze

learning in adulthood. These studies formed the basis of studies on the effects of environmental enrichment on behavior and neural development and have stimulated research on the effects of environmental enrichment on the brain (Nithianantharajah and Hannan 2006).

### The Organization of Behavior

During his years in Florida, Hebb completed the first five chapters of his 1949 book, *The Organization of Behavior*, in which he outlined a new way of understanding behavior in terms of neural function. Hebb became a professor of Psychology at McGill University in 1947, and during his first year in Montreal, he wrote the final chapters for *The Organization of Behavior* in which he proposed a neurophysiological theory for the explanation of psychological concepts such as attention, perception, and learning. He proposed two concepts, synaptic plasticity and cell assemblies, which have since become central tenants in neuroscience (Cooper 2005). Hebb discussed how he came to write *The Organization of Behavior* in his two autobiographical memoirs (Hebb 1959, 1980).

### Hebb's Students and Their Research

Hebb used the theories that he had developed in *The Organization of Behavior* to direct the research of his students at McGill. The publications of his students illustrate how Hebb's theories influenced his later research. For example, Rabinovitch and Rosvold developed a standardized procedure for the Hebb–Williams maze and tested rats with cortical damage and rats reared in a “free environment.” Other students used the Hebb–Williams maze to test the effects of environmental experience and lesions, thalamic stimulation, and the effects of environmental enrichment on learning and memory. Rosvold and Mishkin looked at the effects of prefrontal lobotomy, and Brenda Milner looked at the intellectual function of the temporal lobes. This research led to the groundbreaking work on patient HM, which revolutionized the study of the neural basis of memory. Hebb also continued

his studies of fear and emotionality using pure-bred Scottish terriers to examine the effects of early-rearing experience (enriched and isolated) on learning and in studies of emotional behavior and the development of social behavior. Some of the most famous work from Hebb's lab was that of Olds and Milner on electrical stimulation of brain reward pathways in the brain and the work on sensory deprivation. See Brown (2007) for detailed references.

### Hebb's Writings After *The Organization of Behavior*

With the completion of *The Organization of Behavior*, Hebb became a major theorist in the field of physiological psychology and reviewed the field for the first *Annual Review of Psychology*. In “The role of neurological ideas in psychology,” Hebb discussed his theory of behavior in comparison to the theories of Tolman, Krech, Hull, and the Gestaltists. In a 1953 lecture to the British Animal Behavior Society, he examined the problem of separating genetic and environmental components of behavior. In his presidential address to the Canadian Psychological Association, he argued that human thought was the central problem for psychology (Hebb 1953). With Thompson, Hebb wrote a chapter on the social significance of animal studies for the Handbook of Social Psychology which suggested that emotionality and psychopathology result from breakdowns in cell assemblies. In his presidential address to Division 3 of the APA, Hebb (1955) discussed the concept of motivation in terms of the CNS (conceptual nervous system). In this paper, Hebb presented the idea of an inverted U-shaped curve for the optimal arousal of behavior. Hebb wrote this paper in response to B. F. Skinner who wrote that the letters CNS should “be regarded as representing not the Central Nervous System, but the Conceptual Nervous System.” In his presentation to the American Psychiatric Foundation, Hebb again discussed the importance of environmental stimulation during development, relating it to levels of adjustment at maturity. Hebb taught the introductory psychology course at McGill for many years and wrote his *Textbook in Psychology* in 1958.

## The Long-Lasting Influence of Hebb's Ideas

In 1977, Hebb retired to Chester, Nova Scotia. He became a professor emeritus at Dalhousie University and wrote his third book, *Essay on Mind*, a summary of his ideas on the biological basis of behavior, in 1980. After Hebb died in August 1985, a number of obituaries were published which described his legacy in every area of psychology and neuroscience (e.g., Harnad 1985; Klein 1989). Hebb's influence on research in psychology and neuroscience is now greater than ever (Brown 2017). His ideas continue to stimulate research in neural and behavioral epigenetics, the long-term effects of environment on health and cognition, the physiological mechanisms of learning and memory, memory span, and language learning. Hebb's influence is also pervasive in studies of computer modeling of the brain and in robotics in which Hebbian learning rules are used to control brain–robot interfaces (Tetzlaff et al. 2015). Posner and Rothbart (2007) have gone as far as to suggest that Hebb's ideas could be used to integrate the cognitive, behavioral, and physiological approaches in psychology.

## Dopamine Receptor

Raymond Turco  
Hunter College, New York, NY, USA

## Synonyms

DRD

## Definition

A class of G-protein-coupled receptors whose endogenous agonist is the neurotransmitter dopamine.

## Introduction

The neurotransmitter dopamine plays a significant role in influencing locomotor activity, attention, motivation, positive reinforcement, cognitive functions, and hormonal regulation as it interacts with a family of G-protein-coupled receptors. The main dopamine systems arise from the midbrain and the hypothalamus. Dysregulation of dopamine is suggested to be at the root of a number of major neuropsychiatric disorders (Daly and Salloway 1994).

## The Dopamine System

The cells of the midbrain that involve dopamine can be divided into the three groups: A8 in the retrorubral field, A9 in the substantia nigra, and A10 in the ventral tegmental area. Neurons found in the retrorubral field and the substantia nigra ascend to the striatum to form sections of the extrapyramidal system, a network that governs and coordinates involuntary movement. Neurons in the ventral tegmental area project to the limbic and cortical areas, forming the mesolimbic and mesocortical tracts. These neurons may be involved in emotional expression and cognitive functioning (Daly and Salloway 1994).

## Subtypes

There are five different types of dopamine receptors, divided into two classes, activation (D1 and D5) or reduction (D2, D3, and D4) of cyclic AMP (adenosine 3':5'-monophosphate; cAMP) (Binder et al. 2009). cAMP, or cyclic AMP, is an intracellular second messenger generated by adenylyl cyclase and deriving from ATP (Offermanns and Rosenthal 2008).

## D1-like Family (Activation)

### D1

Dopamine receptor D1 is by far the most abundant subtype in the brain, found in elevated concentrations in the substantia nigra pars reticulata, the caudate, the putamen, the nucleus accumbens, the olfactory tubercle, and both the front and temporal lobes (Daly and Salloway 1994). It is encoded by the DRD1 gene and is found postsynaptically on such dopamine-receptive cells as the GABA-ergic medium spiny neurons (MSNs) in the striatum (Beaulieu and Gainetdinov 2011). D1 receptor activation on postsynaptic neurons is especially associated with a stimulatory effect on locomotor activity. As a whole, D1 receptors regulate neuronal growth and development, mediate some behaviors, including reward, and also modulate D2 receptor-related events (The National Center for Biotechnology Information 2017).

### D5

The roles of the D5 receptors remain less clear than the roles of the D1 and D2 receptors. However, the D5 receptors can be found at low levels in a variety of brain regions, including the pyramidal neurons of the prefrontal cortex, the premotor cortex, the cingulate cortex, the entorhinal cortex, substantia nigra, hypothalamus, the hippocampus, and the dentate gyrus. A very low level of expression has also been observed in the MSNs of the caudate nucleus and nucleus accumbens. It is thought that D5 might have some slight control over movement, and even possible control over cognitive functioning that involves the hippocampal regions (Beaulieu and Gainetdinov 2011).

## D2-like Family (Reduction)

### D2

Along with D3 receptors, D2 receptors are expressed both postsynaptically on dopamine target cells and presynaptically on the dopaminergic neurons. At its highest levels, D2 receptors are found most in the striatum, the nucleus accumbens, and the olfactory tubercle. Additionally, they are found in significant quantities in the substantia nigra, the ventral tegmental area, the

hypothalamus, the cortical areas, the septum, the amygdala, and the hippocampus (Beaulieu and Gainetdinov 2011). D2 is also expressed in the retina and the kidney.

D2 receptors play a role in a number of bodily processes, including locomotor activity. Activation of the D2-like family of autoreceptors on the presynapse causes a decrease in dopamine release that reduces locomotor activity, whereas a corresponding activation on the postsynapse leads to the stimulation of locomotor activity. D2 receptors appear to be heavily involved in the presynaptic regulation of the firing rate, synthesis, and release of dopamine (Beaulieu and Gainetdinov 2011). Importantly, the two splice variants of D2 receptors, D2S and D2L (“Short” and “Long” respectively), have differing neuronal distributions: D2S is largely found presynaptically, while D2L is mainly postsynaptic. D2, in tandem with D1, is responsible for learning and memory functions, as related to the prefrontal cortex. D2 receptors also mediate prolactin secretion as well as take on a variety of other roles outside the central nervous system (Beaulieu and Gainetdinov 2011).

#### D3

Receptor D3 is similar yet distinct from D2 in that it is only a presynaptic receptor. It is found in the olfactory tubercle, the nucleus accumbens, the striatum, the substantia nigra, and the hypothalamus, and may in fact play the role of an “autoreceptor” as suggested by its presynaptic location and high affinity for dopamine. It can then be said that D3 may monitor the amount of synaptic dopamine in the brain (Daly and Salloway 1994).

D3 receptors are also found in the islands of Calleja, in the temporal lobe of the brain. Due to their mentioned role as autoreceptors, it seems that D3 moderately inhibits locomotor activity and, moreover, may be involved in cognitive functions that are mediated by the hippocampal regions, just as has been found with D5 (Beaulieu and Gainetdinov 2011).

#### D4

The D4 receptor is distributed across the frontal cortex, the medulla, the hypothalamus, and to a

lesser degree across the basal ganglia (Daly and Salloway 1994).

D4 has the least amount of expression of all the receptors. Like D5, D4 has only a minimal influence on movement, and like D3, it may play a role in the cognitive functioning mediated by the hippocampus. Along with both D3 and D5, the physiological role of D4 remains rather unclear (Beaulieu and Gainetdinov 2011).

## Links to Pathology

### Attention-Deficit-Hyperactivity Disorder

It is hypothesized that people with Attention-Deficit-Hyperactivity Disorder (ADHD) may have inefficiency in processing dopamine in the frontal lobes and within the frontostriatal neuronal circuitry to such an extent that a significant amount of dopamine is removed from their brain by way of a high instance of dopamine transporter levels (Ferrell 2010; Hedlund 2013). This seems to play a role in causing the hallmark symptoms of impulsivity, hyperactivity, and inattention (Ferrell 2010). Dopamine receptors D4 and D5 have been especially implicated in this pathological process (Miller 2011).

### Substance Abuse and Addiction

The mechanisms behind the action of drugs such as cocaine, amphetamines, and nicotine have been said to involve dopamine (Bough et al. 2015).

Cocaine binds to the dopamine transporter and blocks its functioning, causing dopamine to accumulate within the synaptic cleft. This results in extended and enhanced dopamine signaling. After sustained cocaine use, decreased dopaminergic signaling may be the culprit in depressed mood disorders and the sensitization of the meso-dopaminergic circuit toward cocaine’s reinforcement, leading to dependency (Bough et al. 2015).

Amphetamines cause the release of dopamine from the mesocorticolimbic system and the nigrostriatal neurons, inhibiting some metabolic enzymes and acting as a direct agonist on serotonin receptors (Bough et al. 2015).

Nicotine consumption, such as through tobacco use, increases dopamine levels and

stimulates the reward and pleasure pathways as nicotine receptors bind to the brain. After long-term exposure to nicotine, addiction may become an issue (Bough et al. 2015).

### Schizophrenia

Schizophrenia is a severe mental illness, notable especially for its psychotic symptoms, diminished affect, and cognitive abilities. The dopamine hypothesis as proposed by Arvid Carlsson in 1963, which states that elevated dopamine transmission contributes to schizophrenia's symptoms, is still well-regarded today and came about through experimentation with first-generation antipsychotics. More modern revisions to the hypothesis have specified locations of hyperactive dopamine transmission in the mesolimbic areas and prefrontal cortex, as well as the amygdala (Brisch et al. 2014).

A decrease of D1 receptors in the prefrontal cortex is seen in schizophrenia patients, which contrasts with the elevated expression of D1 in the parietotemporal cortex. A significant increase of D2 in the striatum of schizophrenia patients has been noted as well. The decrease of D2 in the thalamus and anterior cingulate cortex may point to abnormalities in transmission from these regions to the prefrontal cortex. Both types of neuroleptics, typical and atypical, increase the expression of high-affinity D2 receptors, as do dopamine antagonists and agonists. High-affinity D2 expression in large amounts has been seen as an indicator for psychosis. In this way, antipsychotic treatment may be seen to fail in some patients because it elevates this sort of D2 expression that is associated with the increase of psychotic symptoms themselves (Brisch et al. 2014).

It is clear that every effective neuroleptic that has been formulated has had some connection to the neurotransmitter dopamine as it interacts with other neurochemicals such as glutamate, GABA, serotonin, and acetylcholine (Brisch et al. 2014).

### Parkinson's Disease

Parkinson's is primarily considered a neurodegenerative movement disorder as it involves resting tremors, rigidity, postural instability, and freezing, among such other complications as depression,

sleep disturbance, and dementia, the last one occurring especially in the late stages. Dopamine is thought to be at the root of this symptomatology, though the disease affects multiple systems (Prediger et al. 2014). The degeneration of dopaminergic neurons in midbrain nigrostriatal pathway, and thus the decline of midbrain dopamine transmission, has been pointed out as a particular focal point of the disease's etiology (Prediger et al. 2014; Double and Finberg 2016). The work of Arvid Carlsson and the prescription of L-Dopa, a medication that elevates dopamine levels, contributed greatly to the advancement of knowledge on the neurobiology behind Parkinson's (Double and Finberg 2016). Agonistic activity on D2 receptors through medication contributes to the reduction of Parkinson's symptoms, but may lead to side effects such as the vomiting, hallucinations, and hypotension associated with elevated dopamine levels (Prediger et al. 2014).

### Dopamine and the Animal Kingdom

Dopamine controls locomotor activity in animals and other vertebrates just as it does in humans. Additionally, the reward mechanism that involves dopamine has been identified through single-cell recording of dopamine neurons in animals, and dopamine has been implicated in the biology of depression in animals. However, dopamine's role in depression has been found less in humans (Blanco 2017). It is with studies involving D2 receptor-deficient mice that dopamine involvement in locomotion and reward systems has been substantiated (Oak and Van Tol 2008).

In speaking about the confluence of dopamine, animals, and reward, it is important to mention temporal difference learning. Temporal difference learning is a reinforcement-learning algorithm that learns to predict future rewards through a reward-prediction error signal, and is especially used as both a model for animal learning and dopamine activity (Seel 2012). The algorithm is an estimation tool in a way, in that it compares the prediction of a future reward to the observed reward and the estimated value of the next state. In a series of important studies, Wolfram Schultz

and his colleagues found that during classical conditioning with monkeys, dopamine neuron firing corresponded strongly with the temporal difference learning model in that dopamine neurons fired to unexpected rewards that have no precedent. This is due to a significant prediction error, as expressed by temporal difference algorithm. Dopamine neurons stopped firing after exposure to a consistent reward as suggested by the model, i.e., when subjects' predictions matched reward outcome. The temporal difference model is the dominant theory of the dopamine response to learning and has since been suggested as the basis for other models of learning beyond classical conditioning. Investigation has branched out to other subject models, including humans and rats, and other fields beyond reinforcement learning, including the burgeoning realm of neuroeconomics. The outlook is bright for further studies on this topic (Ludvig 2012).

Mice lacking in dopamine transporter show signs of hyperactivity, possibly due to a hyperdopaminergic state, and animals deficient in D2 receptors show dopamine autoreceptor-mediated cell firing inhibition (Harsing 2008). The dopamine overflow, caused by the stimulant methylphenidate, that leads to greater potentiation in dopaminergic drugs was first demonstrated in animal testing (Harsing 2008).

<sup>3</sup>The Ohio State University – Mansfield, Mansfield, OH, USA

## Introduction

Through their use of playback experiments on wild primates, Dorothy Cheney and collaborator Robert Seyfarth inspired cross-disciplinary scholars of animal behavior for decades. Cheney and Seyfarth are not only pioneers in questions about the social lives and minds of animals, they also revolutionized the methods we use to investigate these questions.

## Background

Dorothy L. Cheney was born on August 24, 1950, in Boston. She received her Bachelor's degree from Wellesley College in 1972, her Ph.D. in Animal Behaviour from Cambridge under Robert Hinde in 1977, and completed a postdoctoral position with Peter Marler at Rockefeller Center in 1979. After a tenure-track stint at Rockefeller Center and UCLA, she joined the University of Pennsylvania in 1985, where she remained as a Professor of Biology until her retirement in 2016. Cheney is a fellow of the Animal Behavior

Society (1997) and American Academy of Arts & Sciences (1999) and was elected to the US National Academy of Sciences (2015). She holds an honorary Ph.D. from University of Neuchâtel, Switzerland (2013), received the Distinguished Primatologist Award from the American Society of Primatologists (2016), and accepted the Distinguished Animal Behaviorist Award from the Animal Behavior Society (2016).

Cheney married Robert Seyfarth in 1971, and the couple had two children, Caroline and Lucia. Cheney and Seyfarth conducted joint field research together throughout their careers (frequently joined by their daughters), focusing on communication, cognition, and social behavior of wild monkeys. Their award-winning book *How Monkeys See the World: Inside the Mind of Another Species* (Cheney and Seyfarth 1990) is an engaging summary of their 11 years spent studying vervet monkeys in Amboseli National Park. Similarly, *Baboon Metaphysics: The Evolution of a Social Mind* (Cheney and Seyfarth 2007) describes their 16 years of research on baboons in the Okavango Delta. Counted among its many accolades, *Baboon Metaphysics* was runner up for The Diagram Prize for Oddest Book Title of the Year by *The Bookseller* magazine, losing to *The 2009–2014 World Outlook for 60-milligram Containers of Fromage Frais*. Combining careful science with their clever writing style, Cheney and Seyfarth develop an argument in both of their books for the adaptive value of social cognition. They encourage the reader to look behind the curtain to explore the many surprising ways these animals are so similar to ourselves and, perhaps more importantly, where they differ in their cognitive and communicative abilities.

Cheney and Seyfarth have published over 200 articles, commentaries, and book chapters – 90% of these written together – on their original empirical work (many in collaboration with colleagues and students) or that review the implications of such work. Their major contributions are in social cognition and vocal communication. We focus on social cognition in this entry, but to understand Cheney's impact on communication, see Robert Seyfarth's entry in this series. Tales of Cheney and Seyfarth's narrow escapes from

hippos, lions, and malfunctioning vehicles are best communicated by the authors themselves.

## Contributions to Social Behavior and Social Cognition

As an undergraduate History major, Cheney was not particularly captivated with biology, until a course in the history of science piqued her interest in the evolution of sociality. After spending a year helping Seyfarth with his graduate fieldwork studying primate social relationships, she shelved her plans to attend law school and focused instead on figuring out what monkeys know about each other and their world.

A fortuitous result in what seemed a straightforward experiment in individual vocal recognition (Cheney and Seyfarth 1980) led to a career focused on social cognition. In the experiment, Cheney and Seyfarth played the recorded screams of juvenile vervet monkeys to a group of females with juvenile offspring, including the screamer's mother. They expected that, if vervets can recognize the vocalizations of other individuals, the mother of the screaming juvenile would respond more strongly to the playback (for example, by quickly looking toward, staring at, and/or approaching the hidden speaker) than would the control females. That is exactly what they found; however, they also recognized that they had a much more interesting result. Many of the control females had looked not at the speaker, but toward the screaming juvenile's mother, even before the mother had made any obvious response. Cheney and Seyfarth recognized the value of the unexpected finding – it demonstrated that vervet monkeys could associate a juvenile's scream with its mother, suggesting that the monkeys could make complex classifications of vocalization based on social relationships. Although identifying relationships between others (3rd party relationships) is second nature to humans, at the time, there was very little evidence that animals had similar abilities.

Further studies of vervets and baboons provided additional evidence that monkeys could indeed recognize 3rd party relationships. For

example, Cheney and Seyfarth (1989) observed female vervets for half an hour before and after fights to compare their behavior toward relatives of their opponents. They found that, after a fight, females were both more likely to threaten and more likely to behave affiliatively toward the relatives of their opponent than they were in the control period before the fight. Similarly, kin of the two opponents were also more likely to threaten or be friendly toward each other following a fight than in the control period. The vervets acted as though they recognized the similarity between their own close relationships and those of others. Although the vervets' differential treatment of kin could be explained as simple associative learning based on frequently observing kin together, Cheney and Seyfarth noted that kin relationships among the vervets were not necessarily characterized by frequent interactions. Instead, they posited that the monkeys might understand kin relationships as an abstract category that could not be entirely explained by close bonds. The ability to classify relationships in this way could be highly adaptive, since it could allow the monkeys to predict the likely behavior of others.

An elegant playback experiment by Cheney and colleagues (Bergman et al. 2003) produced strong evidence that baboons classify individuals by both rank and kinship. Female baboons have a linear dominance hierarchy, and they "inherit" their mothers' ranks. That is, young females typically attain dominance ranks immediately below those of their mothers. As a result, entire matriline can be organized in rank-order. For example, if female A1 has two offspring, A2 and A3, they rank above female B1 and her offspring, B2 and B3, such that  $A1 > A2 > A3 > B1 > B2 > B3$ . Bergman and colleagues took advantage of this structure to test whether baboons reacted differently to simulated rank reversals within compared to between matriline. In their experiment, they mimicked fights in which an aggressor threatens and a victim screams. In the control scenario, they simulated a normal interaction, with a high-ranking aggressor threatening a lower-ranking victim (A3 threatens, B1 screams). They compared the responses of females to the control scenario to their responses to simulated

within-family rank reversals (A3 threatens, A2 screams) and between-family reversals (B1 threatens, A3 screams). Even though the magnitude of the rank difference was similar in both within- and between-family reversals (in this example, the ranks are adjacent), the baboons reacted more strongly to the between-family reversal than to the within-family reversal or the control. The results made it clear that baboons were sensitive not only to the rank relationships of other individuals, but also to membership in higher-order groups, such as matriline.

In a similar vein, Cheney and colleagues (Crockford et al. 2007) demonstrated that baboons are well aware of even short-term changes in the quality of others' relationships, taking advantage of the transient nature of baboons' mating relationships. High-ranking male baboons frequently form consortships with estrus females in which the male closely follows and guards the female from other males' sexual advances. The consortships are short-lived, usually lasting several hours to several days. Crockford and colleagues mimicked broken consortships by playing the friendly grunts of a male from one speaker immediately followed by the mating call of his consort partner from another speaker positioned 40 m away – far enough apart that it seemed as though another male must have elicited the consort's mating call. They compared the responses of males to these simulated breakups to their responses to two controls. In the first control, they combined the friendly grunts of a nonconsorting male with the distant mating calls of the consorting female (consistent with an intact consortship). The second control was identical to the experimental condition, but it was played within 24 h after the consortship had ended. The males looked longer and were more likely to approach the speaker playing the mating call in the simulated breakup than in either control condition. The males' lack of response to the second control (post-breakup) was especially revealing, as it demonstrates that, even though some playbacks occurred as little as 4 h after a consortship broke up, they were already aware of the breakup. This provided evidence that baboons can recognize and categorize different types of

relationships – not just the long-term relationships of relatives but also the short-term associations of mating partners.

Though much of Cheney's cognition research focused on uncovering how monkeys categorized one another, she also ventured into even more complex cognitive processes, such as causal reasoning and theory of mind. To test whether baboons were able to identify causal relationships, Cheney and Seyfarth (1995) compared the responses of baboons to simulated anomalous social interactions to a logically consistent control. Anomalous interactions were mimicked by pairing the friendly grunts of a low-ranking female with the fear barks of a high-ranking female, as if the higher-ranking female were deferring to the lower-ranking female. Control playbacks were identical to the anomalous playbacks, except that the friendly grunts of a third female, dominant to both of the others, were included in the sequence, creating a causally consistent scenario in which the high-ranking female appeared to be deferential to an even high-ranking individual. The baboons responded more strongly to the logically inconsistent call combinations than toward the controls, suggesting that they could recognize cause-effect relationships in the social domain. Previous studies (reviewed in Cheney and Seyfarth 1995) had found monkeys incapable of recognizing cause-effect relationships; however, those studies focused on monkeys' understanding of physical relationships. Cheney and Seyfarth's results emphasized the importance of using socially relevant stimuli in experiments involving highly social, non-tool-using species.

In addition to uncovering what monkeys know about each other, Cheney and colleagues have also examined the impact of social relationships on stress hormones. For example, Beehner et al. (2005) found that female baboons had elevated glucocorticoid (GC) levels when a potentially infanticidal male took over the troop's alpha male position, but only if they had, or were pregnant with, an infant at risk of infanticide. These same females did not have elevated GC levels when a natal male who was unlikely to commit infanticide took over, or when they had friendships with males who might protect their infants.

Cheney and colleagues' more recent work has returned to her original interest in the evolution of sociality, with a focus on the adaptive value of social behavior. Using behavioral and demographic data collected over a 15-year period, Silk et al. (2009, 2010) found that female baboons who had strong, long-lasting bonds with other females lived longer and had offspring who were more likely to survive to adulthood than did females with weaker bonds. Females with high scores on a composite behavioral index of friendly behaviors were more facile at developing and maintaining bonds with other females. In addition, those friendly females showed stronger anticipatory responses to male immigration, increased the number of grooming partners after the death of a close relative, and reacted more strongly to playbacks than did other females (Seyfarth and Cheney 2013). In other words, individuals who are highly attuned to social interactions and engage in prosocial behaviors appear to have a selective advantage over less social and unfriendly individuals.

Although it is quite clear that monkeys do not have a full-blown theory of mind – that is, they are not fully aware that other individuals have different knowledge, emotions, and intentions (Cheney and Seyfarth 1990), there is some evidence that they can use their knowledge of relationships combined with memory of recent interactions to predict the likely behavior of others (Engh et al. 2006). Seyfarth and Cheney (2013) posit that selection favoring prosocial behavior may have produced a very rudimentary or functional theory of mind. Rather than knowing how other monkeys feel, monkeys have evolved to *act as if* they know how other monkeys feel.

Cheney and Seyfarth have had a profound impact on studies of social cognition. They used detailed knowledge of vervet and baboon behavior to design elegant experiments using socially relevant variables. By manipulating vocalizations and social scenarios that were familiar to the monkeys, they were able to ask clear questions about what the monkeys knew. Their own thorough research gave us a window into the rich mental lives of vervets and baboons, and their methods, adopted by other researchers, have provided

insights into the cognitive abilities of many other animals.

## Dorothy Fragaszy

Dorothy Munkenbeck Fragaszy  
Department of Psychology, University of  
Georgia, Athens, GA, Georgia

Dorothy Munkenbeck Fragaszy grew up on a small farm in a rural part of New York, where the family kept horses, sheep, chickens, and occasionally other livestock. She spent much of her free time riding her horse in the woods and fields and trying to help her father (a mechanical engineer and devoted do-it-yourselfer) to construct and fix things. Her professional interests in animal behavior and problem-solving reflect these early experiences. She earned a BS in Psychology at Duke University (1972) and PhD (1978) in Psychology at the University of California, Davis. Her first research, as a graduate student with W. A. Mason in the 1970s, compared the behavior of captive squirrel monkeys (*Saimiri*) and titi monkeys (*Callicebus*) in novel spaces or facing other unfamiliar challenges. One of the more adventurous studies she conducted involved releasing pairs of monkeys one at a time into a fenced one-acre enclosure, where she had constructed aboveground paths in the center area, and retrieving the pair at the end of an hour by offering them a ride home in their familiar travel-box (Fragaszy 1979). Her studies with squirrel and titi monkeys convinced her that one must interpret a nonhuman species' behavior in a captive setting in relation to that species' behavior in natural settings. In the case of squirrel

and titi monkeys, this meant understanding their distinctly different social systems and foraging ecology, among other things. Titi monkeys form monogamous pairs and live in small territories, traveling together during the day to feed on familiar resources in known locations. In contrast, squirrel monkeys live in large groups, travel in large home ranges, and search for food visually. Monkeys of these two species display different priorities for remaining with a pairmate (titis) versus exploring independently (squirrel monkeys), and remaining in familiar places (titis) versus traveling to new places (squirrel monkeys).

In preparation for studying captive capuchin monkeys, she wanted to learn about these monkeys' lives in a natural setting. Accordingly, she studied foraging behavior and time budgets of weeper capuchins *C. olivaceus* in the llanos of Venezuela as a postdoctoral project (Fragaszy 1990). Subsequently, she established a colony of tufted capuchins in 1982 at San Diego State University, where she held her first faculty position. She took the capuchin monkeys with her to Washington State University in 1984, and finally to the University of Georgia in 1990, where she served as Chair of the Behavioral and Brain Sciences graduate program (and its predecessors) in the Psychology Department from 1995 to 2017, and is currently Professor of Psychology. Her research participants from 1980 to the present are primarily humans, capuchin monkeys, and chimpanzees, the latter species with the help of collaborators at the Language Research Center of Georgia State University and the Primate Research Institute of Kyoto University. She has collaborated extensively with Elisabetta Visalberghi, with whom she authored, together with Linda Fedigan, *The Complete Capuchin* (a scholarly book about capuchin monkeys).

Dr. Fragaszy's research contributions to the field of animal cognition concern the genesis and expression of behavioral variability and adaptability. The majority of her publications can be grouped into four domains: behavioral development, problem-solving (with an emphasis on spatial problems), motor skills, particularly manual dexterity and skilled actions with objects, and social influences on learning, including traditions.

Her studies revealed how young primates (monkeys, apes, humans) explore objects and surfaces using species-typical action routines that adults use to find and extract food and to solve instrumental problems (Fragaszy and Adams-Curtis 1991; Takeshita et al. 2005) and how young monkeys in natural settings become proficient foragers, finding and processing sometimes hidden foods, such as beetle larvae hidden under leaves or inside branches, or snails or shelled fruits that must be cracked open. Her work has sometimes indicated similarities in the actions of nonhuman primates and humans with objects and sometimes revealed striking differences. For example, Dr. Fragaszy has shown that capuchin monkeys and chimpanzees can seriate nesting cups effectively using a motor strategy: placing a cup on another and then removing it if it does not fit into the receiving cup, and repeating the sequence until each cup is contained within the one immediately below (i.e., the set is nested). Her subjects could fit a sixth cup, given after they had seriated a set of five cups, into its position in the middle of the set. This finding calls into question the hypothesis that seriating nesting cups necessarily reflects comprehension that a single cup has dual properties (larger than one, and smaller than another), as this task had been conceptualized in the human developmental literature. Perhaps children, when they first begin to seriate cups, begin with a motor strategy as well, only later developing comprehension of abstract properties of the component objects (Fragaszy et al. 2002). Similarly, capuchins and chimpanzees align the long axis of a rod or a cross-shaped object to a cutout using a motor/haptic strategy, essentially moving the object across the surface until they feel it drop into the cutout. In this case, however, even two-year-old children can align the long axis of a rod or a cross-shaped object to a cutout, apparently relying on vision to do so (Fragaszy et al. 2015). This finding suggests one reason why monkeys and apes use objects as tools in more limited ways than humans. Nonhuman primates can bring one point of a long object to a point on a surface, as in probing a stick into a hole, but it seems that they cannot precisely align even one axis of one object to an axis in another object, such as the end of a screwdriver with the notch in the head of a screw.

In the domain of manual dexterity, her studies revealed that capuchin monkeys achieve precision grips in diverse forms, occasionally use compound grips (holding two or more objects in one hand using two or more different grips). These are unexpected achievements for New World monkeys because these monkeys' thumbs do not rotate to face the palm, as do the thumbs of Old World monkeys, apes, and humans. While they use precision grips routinely, she has shown that capuchin monkeys do not use in-hand movements (translating or rotating an object wholly with the fingers of one hand) as do chimpanzees, and both species differ considerably from humans in this domain (Craet et al. 2009). Her work on skilled actions with objects also includes studies of tool use, notably by wild capuchin monkeys using stones to hammer open resistant palm nuts. In a series of field experiments conducted with colleagues at the EthoCebus field site in Brazil, she showed that wild monkeys place nuts on an anvil surface in a predictable orientation, so that the more symmetrically curved sides of the nut face the edges of the hemispheric pit in the anvil, and they use exploratory actions before initiating a strike with a hammer stone, strike with accuracy, and control the stone after the strike. These skills apparently depend on haptic perception more than visual perception. They select nuts to crack and hammer stones with which to crack them taking into account the resistance of the nut to fracture and the composition and mass of the stone (Fragaszy et al. 2010). Kinematic analyses of the striking actions revealed that monkeys modulate features of their movements, such as velocity and amplitude of their striking motions, to accommodate to the demands of the task (whether the nut is starting to crack, for example; Mangalam and Fragaszy 2015) but that they do not control some outcomes of their movements that are characteristic of human skilled percussion (such as regulating the momentum of the stone at impact). Apparently the monkeys can perceive velocity and amplitude of their strikes directly (kinesthetically), as movements of their arms, whereas momentum is a joint function of velocity and the mass of the hammer stone, and cannot be perceived through kinesthesia alone. Taken together, her studies in this area have enriched our

understanding of the perceptual foundations of actions with objects, and of the different constraints faced by different species of nonhuman primates in these actions compared to humans. Her work frames the phenomenon of manipulating objects as a problem of movement coordination and management of degrees of freedom of movement, thus linking the phenomenon of using objects as tools to biology, anatomy, and related fields, such as archaeology and robotics.

Finally, Dr. Fragaszy has contributed to our understanding of how nonhuman animals learn with and from others (“socially biased learning”), leading sometimes to the establishment of traditions in the absence of overt teaching or imitation (Fragaszy 2003). She has argued that we need to recognize the power of social coordination of activity in time and space to support young animals’ learning, and that we need to understand the temporal dynamics of social influence and the role of artifacts on learning to advance theory in social learning and cultural evolution (Fragaszy et al. 2013). In this work, capuchin monkeys provide an interesting case. Adult capuchins are highly tolerant of young monkeys remaining near them as they forage and eat, and the adults’ activity strongly influences the young monkeys’ explorations of food and of areas where adults eat (including where they crack nuts with stones and anvils). Their social dynamics and activity, and the artifacts that the adults produce, support young monkeys’ frequent practice of diverse foraging skills, including using stones and anvils to crack nuts. Practice of relevant actions hones specific motor skills, and it also likely strengthens attentional and memory processes related to these activities. Thus adults scaffold young monkeys’ skilled activity in direct and indirect ways.

Throughout her career, Dr. Fragaszy has consistently sought explanations of behavior in accord with species’ perceptual biases, motor propensities, social proclivities, and motivation to coordinate behavior with others in time and space. Her thinking draws on concepts and methods from developmental psychology, movement science, embodied cognition, niche construction theory, ecological psychology, and dynamical systems theory, as well as ethology. She has pioneered, often together with Elisabetta

Visalberghi, new methods of collecting behavioral data in natural and captive settings.

Dr. Fragaszy maintains national and international research collaborations, most notably codirecting the EthoCebus project in northern Brazil since 2005 with Patrícia Izar (University of São Paulo), and Elisabetta Visalberghi (National Research Council, Italy). Her international outlook is evident in her long service to the International Primatological Society in which she held several elected offices, including Secretary General and President, between 1989 and 2004. Subsequently she served as President of the American Society of Primatologists, and as Editor of the *Journal of Comparative Psychology*. She has served as doctoral advisor to about two dozen PhDs, mentored several postdoctoral scholars and hundreds of undergraduate research assistants, and hosted many visiting international students and researchers.

## Dorsal Pathway

Laura Alonso Recio  
 Universidad a Distancia de Madrid (UDIMA),  
 Madrid, Spain

## Synonyms

[Dorsal stream](#)

## Definition

The dorsal pathway is a visual system that stretches from the primary visual cortex in the occipital lobe to the posterior parietal cortex. Also known as “where” or “how” stream, it seems to be responsible for the location of objects in space and for the guidance of actions (Binkofski and Buxbaum 2013). It has been defined as anatomically and functionally separated from another pathway, known as “what” stream, which is located in a more ventral position and has been related to perception of objects.

## Structural Organization of Visual System

To understand the anatomy and functionality of these two pathways, we must first know the way in which the visual system is organized. More specifically, it is necessary to understand how visual information flows from the retina to the visual cortex and what visual mechanisms exist in the cerebral cortex.

## Visual Processing from Retina to Visual Cortex

The specialization of the ventral and dorsal pathways described above start in the retina instead of in V1. In fact, the visual signals are first captured by the eye through the retina, where two different types of photoreceptor cells are activated: cones and rods. While cones have conical shapes and are indispensable for color processing, rods have a cane shape and are related to the processing of dynamic aspects of the world such as movement. Once cones and rods are activated, they respond stimulating the ganglion cells.

Ganglion cells are also located in the retina and could be divided, as a function of their anatomy and functionality, in magnocellular and parvocellular cells (or M and P cells, respectively) (Purves et al. 2001). M cells represent the 95% of the ganglion cells, have a large receptive field, receive information from rods (i.e., they are necessary for movement and depth processing), and emit rapid and transient responses. By contrast, P cells represent the 5% of the ganglion cells, are characterized by having small receptive field that

receive information from cones (i.e., they are related to color and shape processing), and produce slow and sustained responses. In any case, both M and P ganglion cells are responsible for sending the information from the retina to the lateral geniculate nucleus.

The lateral geniculate nucleus (LGN) is the first relay center for visual information processing in the brain. Each lateral geniculate nucleus consists of six layers that receive information from both eyes (Lynch and Corbett 2013). The two inner layers 1 and 2 receive information from the M-cells and the remaining four layers 3 to 6 receive information from the P-cells. From LGN, M and P cells axons are directed through two independent streams to the primary visual cortex. In this sense, M-cells axons project to layer 4C $\beta$  of the primary visual cortex through the Magnocellular pathway and P-cells axons project to layer 4C $\alpha$  by means of the Parvocellular pathway.

### Cortical Mechanisms for Vision

As already mentioned, visual information reaches the visual cortex from the lateral geniculate nucleus for processing to occur. More specifically, information is first processed by the primary visual cortex, also known as striate or, according to the more recent nomenclature, V1. This cortex is located on the medial surface of the occipital lobe, along the superior and inferior sides of calcarine fissure and corresponds to 17 Brodmann area (Zilles and Amunts 2012). V1 is organized into six horizontal layers and vertical columns with neurons specialized in the processing of specific characteristics of stimuli such as edges, depth, orientation, motion, and color (Remington 2012). “Striate cortex” takes its name from the layers and columns formed in this region. Moreover, V1 is retinotopically organized, so each part of the visual fields is processed by a specific part of the cortex.

From V1, information is directed toward secondary visual cortex, also known as extrastriate, which includes the occipital lobe areas located around the primary visual cortex and corresponds to 18 and 19 Brodmann areas. First, 18 Brodmann area (also known as V2) is

composed by two distinct regions: the prestriate and the inferotemporal cortex. Prestriate cortex is located around the primary visual area and receives input from this and other cortical regions and also from the thalamus. Similarly to V1, V2 process all qualities of the stimuli (color, shape, movement, etc.). Inferotemporal cortex is located in the lower part of the temporal lobe and has been related to agnosia. Second, 19 Brodmann area is composed by V3, V4, and V5, which seem to respond to specific aspects of the stimuli. In this sense, while V3 is sensitive to orientation and binocular disparity, V4 plays a role in color and form analysis of visual stimuli, and V5 is specialized in processing motion and depth.

Once the information has been processed by the primary and secondary cortex, it continues to the association areas, which encompass adjacent parts of the posterior parietal lobe and much of the posterior temporal lobe (see Fig. 1). In fact, from V1 and V2 two separate primary visual systems (i.e., the ventral and dorsal stream) emerge, which are anatomically and functionally independent and go to different areas of the secondary and associated visual areas. Specifically, while ventral stream begins in V1, goes through V2 and V4, and ends in the inferotemporal cortex, dorsal stream begins in V1, goes to V2, V3, and V5, and ends in the posterior parietal lobe (Carlson 2014).

**Dorsal Pathway, Fig. 1** Representation of ventral and dorsal streams

## The Dual-Visual Systems Hypothesis

The existence of the two primary separate visual systems described above was first proposed by Mishkin and Ungerleider (1982) who define multiple visual areas in the cortex of nonhuman primates that are organized into two anatomically and functionally specialized pathways. More specifically, they observed that monkeys with inferior temporal cortex lesions had problems in the recognition and discrimination of visual shapes and objects, while monkeys with parietal lobe lesions had difficulties in analyzing the spatial location, shape, and orientation of objects. Considering the above results, these authors propose a model for visual processing composed by two separate visual pathways, one specialized for “object vision” (i.e., ventral pathway or “what” stream) and other for “spatial vision” (i.e., dorsal pathway or “where” stream). From an anatomical point of view, while the first is originated in the primary visual cortex and ends in the temporal lobe, the second also begins in the primary visual cortex but is directed towards the superior parietal region (Mishkin et al. 1983).

A decade after the appearance of this model, Goodale and Milner (1992) refined the distinction about an “object and spatial vision” systems proposing that both the perception of objects and the analysis of spatial location are processed by both the ventral and dorsal pathways, but in different ways and with different purposes. Specifically, they considered that ventral pathway uses the visual information to create a perceptual representation focused on the objects, with information about their shapes, sizes, colors, orientations, and spatial relations. The aim is to transform the visual inputs into representations that collect the enduring characteristics of the objects and their spatial relationships. On the other hand, dorsal pathway uses visual information to create a perceptual representation focused on the viewer with information about objects’ spatial location in relation to the person, in order to mediate the visual control necessary to act upon these objects. In this way, ventral stream is associated with the identification of goal objects (“vision for perception”) and dorsal stream is associated with the implementation of action directed at these goal objects (“vision for action”).

In sum, this model gives less importance to possible differences in the information received by the ventral and dorsal pathways (visual inputs), but focusses in the way they used it (visual output).

The distinction between two separate visual systems has been confirmed by neuropsychological and neuroimaging studies (Herbart and Hesselmann 2012). In this sense, the distinction between dorsal and ventral processing stream emerged from experimental works exploring neurological patients with lesions in various parts of the cerebral visual pathways that provided evidence of a dissociation between the ability to perceive an object and the ability to direct a movement toward that object. On one hand, it has been observed that patients with damage in parietal cortex who present optic ataxia, a severe impairment related with a difficulty to use the visual information to guide grasping, maintain the ability to recognize this information (Goodale and Westwood 2004). On the other hand, patients with lesions in temporal cortex who present agnosia, an impairment in the perception of objects, have an intact ability to reach these unidentified objects (Goodale et al. 1991).

These results had been confirmed by psychological studies in healthy subjects. For example, Aglioti et al. (1995) showed that automatic and metrics calibrations required for visually guided actions are independent of visual perception. Specifically, they used the “Titchener circles” illusion, also known as Ebbinghaus display, consisting of two target circles of equal size that are surrounded by other neighboring circles, which may be larger or smaller (see Fig. 2a). According to the results, subjects tend to report that the target circle which is surrounded by smaller neighboring circles is bigger than the target circle which is surrounded by larger neighboring circles. Aglioti and colleagues also used a variation of this illusion that consists on the presentation of two target circles of distinct size surrounded by other larger neighboring circles (when target circle is the smallest) or smaller (when target circle is the largest) (see Fig. 2b). In this case, subjects tend to report that target circles were perceptually equivalent when the largest is surrounded by smaller neighboring circles and vice versa. The use of this methodology confirms that participants are affected by this size-contrast

**Dorsal Pathway,****Fig. 2** The “Titchener circles” illusion**Dorsal Pathway, Fig. 3** The Müller-Lyer illusion

illusion. However, the authors also observed that regardless of the judgments made by subjects about circles' size, participants made the correct grip aperture in their hand when they are asked to pick up the target circles.

In the same line, van Doorn et al. (2007) concluded that vision for perception contributes to the selection of an action mode but not to the action itself. These authors used the Müller-Lyer illusion, which consist on an optical illusion in which two or more segments of equal size appear larger or smaller depending on whether the arrows at their ends point inwards or outwards (see Fig. 3). Specifically, they instructed subject to give, among others, a verbal judgment on the segment's size, a manual estimation of the segment's length and a manual grasp to the segment. They observed that subjects' verbal judgment and manual estimation were influenced by the Müller-Lyer illusion. However, the illusion had only a minor influence on the manual grasp.

Other, more recent, evidence of the functional division between these two pathways comes from fMRI studies. For example, James et al. (2002) showed that ventral, but not dorsal, pathway is activated when subjects view the same object from different viewpoints. In contrast, Culham

et al. (2003) observed that dorsal, but not ventral, pathway is activated when subjects made a visually guided grasping. Moreover, it has been observed a dissociation between ventral and dorsal fMRI activation during objects and action recognition (Zachariou et al. 2013).

### Processing Along the Dorsal Pathway

In spite of the great acceptance of the dual-visual systems hypothesis, the distinction between a ventral pathway that mediates object perception and a dorsal stream that supports spatial information processing and visually guided action (Goodale and Milner 1992; Mishkin and Ungerleider 1982) has been revised substantially in recent years (Binkofski and Buxbaum 2013).

Some authors have proposed that the ventral and dorsal pathways are not as independent as the classic model has postulated, but they work coordinately, especially in complex movement. In this sense, when an individual performs a complex movement, the dorsal stream needs to access to the ventral pathway store with the aim of obtaining detailed information about the object. Also, the ventral stream requires obtaining the information with which the dorsal stream works in order to adjust, as much as possible, the internal representation of the object. Different neuroimaging studies have been confirmed this hypothesis showing the existence of direct connections between dorsal and ventral streams (e.g., Cloutman 2013). In addition, some studies with patients and normal control have confirmed this interaction. With respect to the first, it has been shown, for example, that patients with agnosia who present impairment in objects perception with an intact ability to reach these unidentified

objects are unable to grasp objects in more complex task (McIntosh et al. 2004). Regarding the second, some reviewers and meta-analyses have shown that optical illusions like Müller-Lyer or Tichnerer do not influence the dorsal pathway (that is, the manual grasp) because subjects make corrections based on online feedback (e.g., Bruno and Franz 2009; Franz and Gegenfurtner 2008).

Other authors go beyond this interaction and propose that dorsal regions are not only engaged in guided actions but also in the representation of the object shape, even when actions are not required (Freud et al. 2005). More specifically, it has been suggested that dorsal stream is relevant to semantic categorization rather than simply reflecting spatial information processing and visually guided action. For example, Mahon et al. (2010) investigated the neural response associated with different category of objects and observed that dorsal stream was activated during the recognition of tools, but not during the recognition of other objects' categories. They concluded that the ability to recognize manipulable objects associated with specific hand movement (like tools) may also depend on activity of dorsal stream.

With the aim of confirming that the results described above actually reflect the involvement of dorsal pathway in semantic categorization and not only the interaction between the two streams, some authors have employed the Continuous Flash Suppression (CFS), an interocular suppression technique used to manipulate visual consciousness disrupting the ventral stream activation while leaving the dorsal pathway intact (Herbart and Hesselmann 2012). To achieve this, a static picture is presented in an eye, while a set of dynamic pictures appear in the other eye. Using this technique, Almeida et al. (2008) designed a task in which a visible target picture (a tool or an animal) was preceded by a prime picture (congruent or incongruent with the target one) rendered invisible under CFS. Results showed that while congruent primes suppressed facilitated categorization of tools (manipulable objects), they had no effect on animals (nonmanipulable objects).

To explain the variety of function within the dorsal pathway, it has been proposed the differentiation between two anatomically and functionally

different streams: the dorso-dorsal and the ventro-dorsal streams (Binkofski and Buxbaum 2013). While the dorso-dorsal stream projects to the superior parietal lobe and is engaged in the control of actions "on line," the ventral-dorsal stream goes to inferior parietal lobe and is related to space perception and action understanding.

## The Dual-Streams Approach in Other Sensory Systems

The idea of two separate visual processing pathways widely influenced the study of the organization of other sensory processes such as attention, somatosensory, and language processes.

In the case of attention, it has been proposed the presence of a dorsal system responsible for guiding voluntary attention to features or locations and a ventral system related to the detection of unexpected stimuli. From an anatomical point of view, while dorsal system is composed of the intraparietal sulcus and the frontal eye field, the ventral system comprises the temporoparietal area and the ventral frontal cortex. Moreover, it has been described that while dorsal system is organized bilaterally, the ventral system might be more lateralized to the right hemisphere (for a revision, see Vossel et al. 2014). However, it has been suggested, based on empirical findings from human neuroimaging experiments and studies in stroke patients, that these two routes streams do not seem to function completely independently, but there is a flexible interaction between them enabling the dynamic control of attention (Vossel et al. 2013).

With respect to the somatosensory system, different models have been proposed to explain its anatomical and functional organization. For example, Reed et al. (2005) proposed that while form, color, and features are processed in a ventral pathway, which runs from primary sensory cortex to the inferior parietal lobe and the prefrontal cortex, spatial characteristics and motion depend on a dorsal pathway that projects from primary sensory cortex to the superior parietal lobe. Moreover, James et al. (2007) concluded that we can distinguish between a ventral stream specialized

in material properties, including texture, and a dorsal stream related to geometric properties or shape. While ventral stream starts in the primary somatosensory cortex and ends in the lateral occipito-temporal cortex, the dorsal one projects from the primary somatosensory cortex to the posterior parietal cortex.

Finally, the existence of two different streams in language function from the superior temporal gyrus has also been proposed. In this sense, authors have described a ventral stream, which projects to the middle and inferior temporal lobe and is related to meaning, and a dorsal stream, which is directed toward inferior parietal and posterior frontal lobes and has been defined as important to articulation (Hickok and Poeppel 2004). Moreover, it has been proposed that while ventral stream is bilaterally organized, the dorsal stream is more lateralized to the left hemisphere (Hickok and Poeppel 2007). In any case, as it also happens with the visual system, more recent studies have suggested that dorsal stream is also related to syntactic processing, particularly in complex sentences. For this reason, it has been proposed, as in the case of the visual system, the existence of two different dorsal stream (Friederici 2012).

In sum, emerging data from neuroimage and behavioral studies (with healthy and clinical population) reflect the highly complex organization of various sensory processes (not only of the visual system). Future studies should examine in detail the components of different sensory systems, their functions, and the interactions that are established between them.

## Dorsolateral Striatum

Christine Stubbendorff

School of Biosciences, University of Nottingham, Loughborough, UK

## Synonyms

Sensorimotor striatum

## Introduction

The dorsolateral striatum (DLS) is a subcortical structure in rodents, that is homologous to the putamen in primates (Amaya and Smith 2018). DLS is involved in the execution of motor responses (Tang et al. 2007; Costa 2007) and is considered a key brain region for habit formation and the regulation of stimulus-driven behavior

(Balleine et al. 2007; O'Hare et al. 2018). DLS is a crucial part of a wider neural circuitry that integrate environmental cues and generate appropriate behavioral responses to those cues, based on previous experience (Amaya and Smith 2018; Balleine et al. 2009; Peak et al. 2019). Dysfunction in the formation or perseverance of stimulus-response associations has been implicated in Parkinson's disease (Costa 2007) and addiction (Yin et al. 2006) in humans.

## Habitual Behavior

DLS is primarily associated with habit formation and execution of automated stimulus-response behavior (Balleine et al. 2007; O'Hare et al. 2018). Automated stimulus-response behavior develops when an individual is repeatedly exposed to and consistently responds to the same stimulus-response-outcome contingency, leading the individual to form a strong association between the stimulus, response, and expected outcome (Balleine et al. 2007). In a rodent operant conditioning paradigm, the conditioned stimulus could be the presentation of a lever, the conditioned response would be the rodent pressing the lever, and the outcome could be the delivery of a sugar pellet. At the early stages of acquisition, the rodent will focus its attention on producing the behavior that aids it in obtaining a beneficial outcome, i.e., the behavior is goal-directed. This goal-directed stage of acquisition is strongly dependent on activity in dorsomedial striatum (DMS) (Peak et al. 2019). As a task is learned, the response time to pressing the lever gradually decreases as the stimulus-response becomes automatic or habitual (Tang et al. 2007). The change from goal-directed to automated behavior is associated with responding becoming less dependent on DMS and increasingly dependent on DLS (Balleine et al. 2009). The development of automated stimulus-responses are often adaptive, as it decreases response time, and the automatization of routine behavior also allows allocation of attention to other cognitive processes (O'Hare et al. 2018). However, once a stimulus-response has become automatic, it is difficult to

change the behavior, even when it is no longer adaptive. Rats that are overtrained on a lever pressing task become insensitive to changes in outcome value and continue pressing the lever even when the reward is devalued (Yin et al. 2006; Balleine et al. 2009). However, if DLS is lesioned after the task has been learned, sensitivity to outcome value is reinstated (Balleine et al. 2009). In addition, inactivation of DLS disrupts performance of well-learned tasks but does not affect the acquisition of new tasks (Costa 2007). This occurs because when DLS is lesioned or inactivated, the DMS resumes its previous role in mediating striatum-dependent behavior, and as a consequence, the behavioral output becomes more goal-directed (Peak et al. 2019). Similarly, if DMS is lesioned or inactivated, habitual responses increase (O'Hare et al. 2018; Balleine et al. 2009). These studies demonstrate how DMS and DLS form part of parallel and competing neural networks that organize goal-directed and habitual behavior, respectively (O'Hare et al. 2018; Amaya and Smith 2018; Peak et al. 2019; Balleine et al. 2009). Adaptive behavior is achieved by optimizing the balance between automated stimulus-response behavior mediated by DLS and reflective goal-directed behavior mediated by DMS.

## Motor Response

DLS also plays a crucial part in the initiation and fine tuning of motor responses and the majority of neurons in DLS respond to movement (Costa 2007; Amaya and Smith 2018; Tang et al. 2007). With repeated training on a movement-dependent task, motor related neurons in DLS decrease their activity, whereas the smaller population of nonmovement-related neurons increase or maintain their firing rate (Tang et al. 2007; Costa 2007). This suggests that as an automated response is learned, the response moves from being facilitated by a large number of neurons to being modulated by a smaller population of task-specific neurons within the DLS (Tang et al. 2007). In this way, DLS plays a crucial role in the fine tuning of precise motor responses (Amaya

and Smith 2018) which, through repeated pairings of stimulus-outcome associations, optimize motor-dependent behavior toward achieving a desired outcome (Amaya and Smith 2018; Balleine et al. 2009; Peak et al. 2019).

## Corticostriatal Circuitry

The striatum is the main input structure to the basal ganglia and DLS receives strong projections from both primary motor and sensory cortex and is part of a corticostriatal re-entrant circuit, linking cortical, basal ganglia, and thalamic brain regions (Peak et al. 2019; Balleine et al. 2009). Through these connections, DLS-mediated behavior is influenced by changes in this wider neural circuitry. As rats learn an operant task, neuronal activity in primary motor cortex and DLS as well as synchrony between these brain areas increase (Costa 2007; Koralek et al. 2013). Furthermore, neuronal connections within the corticostriatal circuit that are activated or inhibited during the task acquisition are strengthened or weakened to optimize the behavioral output (Peak et al. 2019). The striatum forms a crucial node within this neuronal circuitry and rather than simply conveying information from cortical and thalamic areas, DMS and DLS integrate sensory, cognitive, and motor feedback input to form associations and facilitate adaptive behavior (Peak et al. 2019).

## Dopamine

The majority of neurons in the striatum express dopamine receptors, and fluctuations in dopamine receptor activity within the striatum play an important role in mediating behavioral output (Peak et al. 2019). Neurons in the corticostriatal re-entrant circuitry project through the striatum via two different routes. Neurons in the direct pathway express predominantly D1-like dopamine receptors and project from the striatum to the internal segment of the globus pallidus and the substantia nigra pars reticulata (Peak et al. 2019; Jin et al. 2014). Neurons in the

indirect pathway predominantly express D2-like receptors and project from the striatum to the external segment of globus pallidus which connects reciprocally to the subthalamic nucleus, which in turn project to the internal segment of the globus pallidus (Peak et al. 2019; Jin et al. 2014). Whereas dopamine modulation of D1 dopamine receptors in the direct pathway is thought to facilitate movement, dopamine modulation of D2 dopamine receptors in the indirect pathway is thought to inhibit it (Jin et al. 2014). However, movement initiation is associated with increased activity in both the direct and indirect pathways, which suggests that the roles of the direct and indirect pathways may not be quite so strictly divided (Jin et al. 2014) and activity in both pathways is required to optimize stimulus-response behavior (Amaya and Smith 2018). Activation of dopamine receptors within the striatum plays an important role in both task acquisition and habit formation (Costa 2007; Amaya and Smith 2018), and habitual behavior correlates with increased DLS output to both the direct and indirect pathways whereas suppression of habitual behavior correlates with decreased output to the direct pathway (O'Hare et al. 2018).

## Dorsomedial Area

Hsin-Hao Yu and Marcello Rosa  
Monash University, Clayton, VIC, Australia

## Synonyms

Third-tier visual areas

## Definition

A region of the primate visual cortex that approximately corresponds to the dorsomedial part of Brodmann's area 19.

## Introduction

Since the nineteenth century, when scientists started to recognize that the cerebral cortex is a system consisting of multiple functional modules (or “cortical areas”), the systematic study of how the cerebral cortex is divided into areas (“parcellation”) has been one of the main challenges of systems neuroscience. The visual cortex, being one of the largest cortical systems in many species of mammals, has served as a model system for understanding the basic organizing principles of the cerebral cortex.

In Brodmann's 1909 landmark study of the organization of the cerebral cortex, the visual cortex is situated at the posterior end of the primate cerebral cortex, and it is divided into three areas: 17, 18, and 19 (Fig. 1c, d). Area 17 is positioned at the posterior pole and is surrounded rostrally by the belt-like area 18, which, in turn, is surrounded rostrally by the belt-like area 19. While Brodmann's areas 17 and 18 approximately correspond to the modern concept of the primary (V1) and the secondary (V2) visual areas, contemporary researchers view Brodmann's area 19 as a region consisting of multiple areas. This entry focuses on the current views of the organization of the dorsal and the medial part of Brodmann's area 19 – a region that will be referred to collectively as the dorsomedial visual cortex. Sandwiched between area V2 and the posterior parietal cortex, areas in dorsomedial visual cortex are thought to be part of the “dorsal stream” (or the “where” stream) of visual processing – important for extracting information about motion and spatial relationships in the visual field. The information is then distributed to the parietal cortex to mediate visually driven actions, such as eye movements and goal-directed reaching.

The dorsomedial visual cortex is one of the least explored sectors of the primate visual cortex, and its organization is one of the most controversial. This entry provides a succinct summary about the current state of knowledge about this region, as well as some of the controversies.

**Dorsomedial Area, Fig. 1** (a) Lateral view of the marmoset cortex, showing the parcellation of the visual cortex according to Paxinos et al. (2012). Names within parentheses indicate the names of likely homologous areas in macaque brain. Area 19M mentioned in the entry is located on the medial surface and therefore is hidden from view. (b) The location of the dorsomedial visual cortex in the macaque brain, in dorsal (left) view and medial (right) view. Abbreviations of anatomical landmarks: *pos* parieto-occipital sulcus, *cal* calcarine sulcus, *cgs* cingulate

sulcus, *ips* intraparietal sulcus, *sts* superior temporal sulcus, *ls* lunate sulcus, *cs* central sulcus, *as* arcuate sulcus, *ps* principal sulcus. (c) Medial views of the brains of human (left) and macaque (right) to illustrate the locations of the dorsomedial cortex, with respect to Brodmann's area 17, 18, and 19. In (a) and (b), the figures illustrate left hemispheres. In (c), the figures illustrate right hemispheres. The figures are not shown to scale (Sources: (a) Solomon and Rosa (2014), (b) Pitzalis et al. (2013), (c) Pitzalis et al. (2015))

## Mapping the Visual Cortex

Neurons in the visual cortex respond only to localised regions in the visual field, called their receptive fields. *Visuotopy* is the systematic, point-to-point relationship between the locations of neurons on the cortical surface and the locations of their receptive fields in the visual space.

Visual areas are said to contain *representations* of the visual field because the visual field is mapped onto the cortical surface according to their visuotopy.

Visuotopic mapping is typically accomplished by measuring the electrophysiological responses of single neurons to patterns displayed at different positions in the visual field. More recently,

functional imaging methods are increasingly being used to map large proportions or even the entire visual cortex of individual subjects. In particular, functional magnetic resonance imaging (fMRI) is now routinely used to study the human visual cortex noninvasively.

Although visuotopic mapping is essential for identifying areas, they are not defined solely by their visuotopic maps. Instead, the convergence of multiple lines of evidence is usually needed. In addition to visuotopy, visual areas are also identified by their architectonics (i.e., the cellular composition of the tissue), their connectivity patterns (i.e., the cortical networks that they participate in), and the physiological characteristics of their constituent neurons.

### The Dorsomedial Visual Cortex in New World Monkeys

Although the dorsomedial cortex has been studied in detail in a number of primate species, the precise boundaries of the areas, or even the precise number of areas in this region, have remained open to interpretation. Central to the uncertainty is the extent to which a common scheme applies to all primate species. To understand the origin of these issues, it is useful to review the organizations of the dorsomedial cortex in animals on different branches of the primate evolutionary tree separately.

New World monkeys represent one of the two branches of the family tree of simian primates. Their evolution diverged from that of Old World monkeys and apes about 40 million years ago. The cortical surfaces of many smaller New World monkeys are lissencephalic, meaning that they are smooth, lacking the deep sulci found in the brains of larger monkeys. The simple geometry of lissencephalic brains makes these monkeys ideal models for brain mapping studies, because the entire visual cortex is accessible for electrophysiological recordings, and the results can be interpreted more easily without the need to reconstruct the convoluted 3D geometry of a non-lissencephalic brain.

The nocturnal owl monkey and the diurnal marmoset monkey are the two most well-studied New World monkeys in visual neuroscience. In both species, the dorsomedial cortex is largely occupied by an area called the dorsomedial (DM) area (Fig. 1a; Angelucci and Rosa 2015). Straddled between the dorsal surface of the occipital cortex and the medial wall, DM is adjacent to the rostral border of dorsal V2. Interestingly, whereas in areas caudal to DM, namely, V1 and V2, the representations of the upper and the lower visual fields are separated on the ventral and the dorsal surface of the occipital lobe, in DM, both visual fields are represented in the dorsal surface. DM is therefore situated in a region where the belt-like structure of early visual areas (V1 and V2) makes a transition to a more complex organization, where one area shares boundaries with multiple neighboring areas.

Area DM is surrounded by a number of additional areas, which have been identified as area 19M (also known as the parieto-occipital medial area, or P<sub>Om</sub>), the dorsointermediate area (DI), and the dorsoanterior area (DA) in the marmoset monkey (Fig. 1a). Similar areas also have been identified in the owl monkey (Serenio et al. 2015). Very little is known about the organization and functions of these areas, except that they appear to form a functional network with DM.

An alternative view on the organization of the dorsomedial cortex for the marmoset monkey was proposed by Lyon and Kaas in 2001. This hypothesis is described in a later section.

### Old World Monkeys

In the macaque monkey (*Macaca*), the most well-studied Old World monkey, the dorsomedial cortex corresponds approximately to a region in the parietal-occipital cortex, where three deep sulci meet: the lunate sulcus, the intraparietal sulcus, and the parieto-occipital sulcus (Fig. 1b). The complex geometry of the cortical surface in this part of the brain contributes to a long history of controversy about its organization.

It is well established that the dorsal arm of V2 is located along the caudal bank of the lunate and

the intraparietal sulcus, extending into the medial surface of the hemisphere along the dorsal bank of the calcarine sulcus. As in New World monkeys, it represents the lower visual field. The critical question is: what area(s) lies immediately rostral to V2?

While earlier researchers (Zeki 1969) envisioned a belt-like area V3 adjoining the entire length of V2, subsequent studies indicated that the dorsal branch of V3 does not extend medially into the medial surface of the hemisphere. Instead, starting at the junction of the lunate and the intraparietal sulcus and extending into the medial surface of the hemisphere, V2 is adjoined rostrally by an area called V6 (Gamberini et al. 2015). A noteworthy characteristic of the V6 visuotopy is that the representation of the central visual field is not magnified, meaning that most of the surface area of V6 is devoted to the presentation of peripheral visual field. The emphasis on the peripheral visual field suggests that the functions of V6 have less to do with the fine analyses of the information at the center of gaze, but instead are more associated with navigation and relating the objects at the center of gaze to the environment.

In addition to V6, at least two areas in this region of the macaque brain have been identified: V6A and V3A. Dorsal to V6 on the rostral bank of the parieto-occipital sulcus is a visuomotor called V6A. V6A is divided into a dorsal (V6Ad) and a ventral (V6Av) component, with the ventral part containing more visual neurons than the dorsal part. V6Ad and V6Av do not have precise visuotopy, although the visual neurons in V6Av primarily represent the peripheral visual field, while those in V6Ad primarily present the central visual field. Area V3A is located on the rostral bank of the lunate sulcus, adjoining V3 caudally and V6 medially.

Similar to area DM in New World monkeys, V6 is located in a region where multiple areas share borders with each other.

## Humans

fMRI studies have revealed broad similarities between the organization of the parietal-occipital

cortex in humans and in macaques. An area identified as the human V6 is located in the parieto-occipital sulcus, occupying both banks (Fig. 2a, b; Pitzalis et al. 2015). As in the macaque monkey, the human V6 emphasizes the peripheral visual field and shares borders with multiple areas (V2, V3, and V3A; Fig. 2c, d).

fMRI mapping also has identified a representation of the lower visual field in the dorsal part of the parieto-occipital sulcus, which corresponds to the macaque V6Av. In addition, human V6Ad has also been identified in experiments where the subjects were asked to make finger or arm movements to reach visual targets.

## A Common Organization for All Primates?

The broad similarities observed in the organizations of the dorsomedial cortex for different primate species have motivated efforts to unify them under a common scheme.

One approach is to interpret Old World monkeys and humans data in light of the organization described for New World monkeys. The rationale is that the lissencephalic cortices of New World monkeys are more amenable to high-resolution mapping, and the maps obtained tend to be more complete. The most significant challenge in this approach is that area DM is not commonly accepted as a visual area in macaque monkeys and in humans. A possible solution to this problem was proposed by Rosa and Tweedale (2005), who observed that the union of macaque area V6, the dorsomedial part of V3, and part of the upper quadrant representation in V3A constitutes a visuotopic map similar to the visuotopy of marmoset DM. This region might be interpreted as the homolog of the marmoset DM in Old World primates.

It's also possible to take the opposite position. Lyon and Kaas (2001) proposed a unifying scheme based on the idea that the organization of the dorsomedial cortex in the New World monkey is in fact similar to that of Old World monkeys. Under this view, area DM does not directly adjoin the rostral border of V2. Instead, a

**Dorsomedial Area, Fig. 2** The locations of area V6 in relationship to surrounding areas in humans (**a, b**) and in macaques (**c, d**). In (**a**), the medial view of the inflated human cortical surface (right hemisphere) is illustrated. In (**b**) and (**d**), the cortical surfaces of the human and the macaque brains are “flattened” by a computational

algorithm so that areas in sulci can be viewed. *Light gray* and *dark gray* indicate gyri and sulci. Abbreviations: *a* anterior, *v* ventral, *l* lateral, *m* medial, *cal* calcarine sulcus, *pos* parieto-occipital sulcus, *Cin* cingulate sulcus, *ips* intraparietal sulcus, *sts* superior temporal sulcus (Source: Pitzalis et al. (2015))

previously unidentified thin strip of cortex representing the lower quadrant is sandwiched between V2 and DM. This strip of cortex extends laterally and ventrally to form a complete representation of the visual field surrounding V2, called area V3. A belt-like area V3 that approximately adjoins the rostral border of V2, with a visuotopy that mirrors that of V2, is therefore proposed to be a common feature shared by all primates.

Whether if the theories discussed above successfully explain existing data remains a controversial issue. A third approach recognizes the differences observed in different primate species as genuine organizational variations. In particular, Gattass et al. (2015) observed that the organization of the dorsomedial cortex in the capuchin monkey, a New World monkey with a large and convoluted brain, is more similar to what has been

described for the Old World macaque monkey than those described for the lissencephalic owl monkey and marmoset monkey. He contends that the organization of the dorsomedial visual cortex in lissencephalic monkeys underwent reorganizations in the process of evolution, which resulted in different cortical areas, in comparison to monkeys with larger, gyrencephalic brains.

## Functions

The primate visual cortex can be approximately conceived a hierarchical system, whereby information in a lower-level area is sent to a higher-level area via feedforward connections for more elaborated processing in the higher-level area. V1 receives the majority of inputs from the visual thalamus, and therefore it is considered an entry-

level area in the hierarchy, whereas V2 is considered a second-order area because it receives most of its inputs from V1. Both area DM (in marmosets and owl monkeys) and area V6 (in macaques) receive strong inputs from V1 and V2, suggesting that they can be considered second- or third-order areas mediating relatively low-level visual functions.

Furthermore, the primate visual cortex is commonly conceived as having two main “streams” of processing: areas in the dorsal stream (also known as the “where” pathway or the “how” pathway) are associated with functions related to spatial relationship, motion, disparity, navigation, and guidance for action, whereas areas in the ventral stream (also known as the “what” pathway) are associated with functions related to the analysis of textures and shapes, and the recognition of objects. Area DM in New World monkeys and area V6 in macaques and humans are closely associated with the dorsal stream, as evidenced by the fact that both areas receive strong connections from layer 4B of V1, a layer with many direction-selective neurons and projects primarily to dorsal stream areas. Furthermore, DM and V6 are directly connected with other dorsal stream areas, such as the middle temporal (MT) and the medial superior temporal (MST) areas. As well as areas in the posterior parietal cortex, which mediates functions associated with eye movements and reaching.

The response characteristics of neurons in the macaque V6 have been investigated in some detail. As expected for a dorsal stream area, the majority of V6 neurons are selective to the directions of moving patterns, as well as to the patterns of coherent motion generated when a person moves in a complex environment (optic flow fields). Similar responses have also been demonstrated in human V6 using fMRI, which provide strong evidence for the homology between V6 in the two species. Selectivity for patterns of optic flow fields is a response characteristic found in neurons in other areas in the dorsal pathway, such as area MST. It is important for visual functions such as determining the direction of heading as one moves in the environment and for inferring

the distances to objects in the environment during locomotion.

Area MT has been traditionally considered the central node of the dorsal pathway, due to the prominent presence of a large population of direction-selective neurons in this area. In recent years, however, studies of V6 have motivated the recognition of two major motion areas in the dorsal pathway – area MT, the lateral motion area, and area V6, the medial motion area. Although the two areas are heavily interconnected and must have overlapping functions, their roles in vision appear to have different emphases. For example, V6 is more involved in the processing of self-motion, due to its more expanded representation of the peripheral visual field and its selectivity to flow field patterns. MT, on the other hand, has an expanded representation of the central visual field and therefore is more important in the processing of object motion.

In addition, V6 is directly connected to V6A and areas in the posterior parietal lobe, which contain visuomotor neurons that are activated during the movements of the arm, head, and eyes. It is therefore likely to have important functions in visually guided actions.

Clinical studies have provided valuable information about visual areas surrounding the parieto-occipital sulcus. Patients with lesions in this region of the visual cortex have been reported to exhibit optic ataxia – a condition where the patients misreach objects under visual guidance. Some patients have been reported to have motion recognition deficits. Epileptic seizures originating in this region can also produce hallucinations of self-motion. These symptoms are consistent with the known function of areas V6 and V6A.

Very little is known about the functions of the dorsomedial cortex of the marmoset monkey. Although the overall connectivity pattern of the marmoset DM is very similar to that of the macaque V6, DM is connected to ventral stream areas, but V6 is not. DM therefore is expected to mediate a mixture of dorsal stream and ventral stream functions. In accordance to this expectation, populations of DM neurons that are selective to the orientation and the direction of gratings have been reported.

## Synonyms

[Energy](#); [Motivation condition](#)

Among many other ordinary meanings not relevant here, the English Oxford Living Dictionary defines “drive” (<https://en.oxforddictionaries.com/definition/drive>) as a verb meaning “Propel or carry along by force in a specified direction,” “provide the energy to set and keep,” “Urge or force (animals or people) to move in a specified direction,” and “Cause (something abstract) to happen or develop.” The dictionary also includes the following meanings as a noun in psychology: “an innate, biologically determined urge to attain a goal or satisfy a need” and “determination and ambition to achieve something.” Among the synonyms are listed “motivation” and “energy.” Lemon’s 1783 dictionary of English etymology lists the following meaning for “drive:” “to thrust, push, shove before one.”

In the same dictionary, “state” (<https://en.oxforddictionaries.com/definition/state>) is mostly used as a noun to mean “the particular condition that someone or something is in at a specific time” and “a physical condition as regards internal or

molecular form or structure.” Thus, focusing on the above meaning for psychology, “drive state” could be defined as a “particular condition that is innate and biologically determined, and which urges, pushes, energizes, or moves an animal to attain a goal or satisfy a need.”

This definition captures typical uses of the expression “drive state” in psychology, although some details vary across different uses. Uses also include a close relation between drive and motivation but not quite the aforementioned synonymy. For example, Young (1936) began the chapter entitled “The energetics of behavior” with the following quote that he attributed to child psychologist Florence L. Goodenough (1886–1859): “The literal meaning of motivation is the process of inducing movement” (p. 48). Throughout his book, Young views drive and motivation as closely related but not identical:

... motivation is the process of producing movement. ... it is the liberating of “bound” energy so as to induce reaction. The greater the amount of energy liberated in a given situation, the greater the degree of drive. *Drive is energy.* (p. 78, emphasis added)

Young attributed the first use of the term “drive” in psychology to Woodworth (1918), who identified “the problem of drive” as raising the “Why” questions in psychology. The other kind of problem central to psychology, according to Woodworth, was “the problem of mechanism,” which raised the “How” questions. Woodworth related the two kinds of questions thusly: “This distinction between drive and mechanism may become clearer if we consider it in the case of a machine. The drive here is the power applied to make the mechanism go; the mechanism is made to go” (p. 37). According to Young, Woodworth “derived the term [“drive”] from mechanics; a machine must be driven if it is to move, and the drive of a machine is the supply of energy that puts the mechanism in motion” (Young 1936, p. 71).

Woodworth was influenced by Sigmund Freud. Indeed, shortly before Woodworth’s book, Freud (1915) used the German word “trieb” – translated as “drive,” “impulse,” or “urge” – to characterize human motivation. In Freud’s theory of motivation, instincts were the

causes of animal behavior, but he reserved the term “instinct” for nonhuman animals and rarely applied it to humans, using instead the term “drive” to refer to the cause of humans’ behavior.

Thus, contrary to ordinary uses, early psychologists did not quite use the two terms as equivalent. They used “drive” to refer to energy and “motivation” to refer to the result of a drive as energy, although this result is not the same as an animal’s movement. Movement is overt behavior, whereas “motivation” presumably refers to an internal, covert condition. Thus, it is not entirely clear how drive and motivation differ as internal conditions. Energy, of course, is a central concept in physics, especially *thermodynamics*, the branch of physics concerned with how energy relates to temperature and *entropy* (roughly, a measure of the disorder of a system, which is internal to it as well). If drive is energy, perhaps motivation could be analogous to entropy.

Freud (1895), in an unfinished work, was the first to try to apply Hermann von Helmholtz’s (1821–1894) thermodynamics concepts of free and bound energy to theorize about human psychological phenomena. This work was the beginning of what came to be called “psychodynamics” and went later on by the more familiar name of “dynamic psychology” (precisely, the title of Woodworth’s book). The term “dynamic” in this label thus likely comes from “thermodynamics.”

As is also well known, Freud called psychological drive “libido” and reduced it to sex drive, surely too restrictive a concept of a psychological drive. More importantly, Freud built his theory on assumptions that were soon discredited in biology, specifically, Haeckel’s biogenetic doctrine (“Ontogeny recapitulates phylogeny”) and Lamarckian inheritance of acquired traits (see Gould 1977, pp. 155–164). Freud’s drive theory thus soon became a dead end in the scientific study of drives.

Thermodynamics, however, was much more than just von Helmholtz’s concepts of free and bound energy, and nothing in it implied (or presupposed) Freud’s discredited assumptions. Alas, no other early drive theorist in psychology after Freud delved into thermodynamics as further developed by others (e.g., Boltzmann,

Gibbs, Maxwell, Planck, etc.). Who knows how the concept of drive in psychology, and the theories based on it, might have developed had early drive theorists after Freud used amore developed thermodynamics, without following his lead in reducing psychological drive to sex drive and adopting those assumptions. Much later, Krebs and Kornberg (1957) in biology seized the opportunity, initiating the very fruitful area of biological thermodynamics (see Haynie 2008).

In a landmark paper almost a decade before Krebs and Kornberg's seminal book, Shannon (1948) proposed his famous information theory, based on the thermodynamics concept of entropy. This theory has been very influential in biology (although it is nowhere to be found in Krebs and Kornberg's seminal book). The theory has also been very influential in information-processing approaches to cognitive psychology, but this influence never quite reached traditional theorizing about drives and motivation in psychology. At least, contemporary information-processing approaches to learning (e.g., Gallistel and Balsam 2014) do not include theorizing about drives or motivation. Nor have theories of drive and motivation in psychology (e.g., Baumeister 2016; Bolles 1975) made much use of information-theoretic concepts either.

None of this is surprising, given that information theory was designed for symbolic systems, and it is far from clear how drives can be conceived as symbolic in nature, beyond the all-too-easy metaphor that they “inform” or “tell” the animal it is time to, say, eat. Fortunately, nothing in thermodynamics *implies* that thermodynamic systems (heat engines) are symbolic in nature (of course, they *could* be conceived as symbolic, but this, in and of itself, is hardly a strong reason to do it; the issue is not whether it *can* be done, but *why* do it). Nor does information theory, as successful as it has been, imply that all systems to which thermodynamics is applied are symbolic in nature either. Thus, a nonsymbolic thermodynamics approach to drives, and how they relate to and differ from motivation is entirely possible. But then again, early drive and motivation theorists in psychology never explored this possibility. What if they had? How would their concepts and

theories have developed had they used thermodynamics? These are interesting questions in counterfactual history better left for another occasion.

Counterfactual history aside, uses of “drive” in early psychology remained standard for decades. Such uses attempted to explain behavior in terms of *internal* efficient causes, the factors that mechanically *pushed* animals, seemingly often purposefully, towards particular aims or goals (see “Goal,” this volume). The concept has often been related to that of *homeostasis*, a biological equilibrium or balance towards which animals supposedly strive. Thus, drive states have been often conceived as means for animals to restore homeostasis (Bolles 1975). As such imbalances become more severe, the concomitant drive states become stronger, which supposedly increases the likelihood that an animal will respond in certain ways under certain conditions.

Some biologists during the 1950s and 1970s viewed drives as *instincts* and proposed them as the main proximate (ontogenetic, as opposed to distal or phylogenetic) causes of animal behavior in their natural environments. This view dominated the works of European biologists Lorenz (e.g., 1966) and Tinbergen (e.g., 1951), who received the Nobel Prize in 1973. They and others ushered the beginnings of ethology, literally “study of behavior,” framing it squarely within biology, with an emphasis on innate behavior. Such framing, of course, was strongly Darwinian, where drives qua instincts were viewed as *adaptations*, phenotypic traits that were present in current animals for having increased their ancestors’ reproductive success. The conditions under which such ancestral adaptive value obtained constituted distal causes of animal behavior.

The notion of an instinct also favored explanations of adaptive behavior in terms of “biological programming”: Animals behaved in the way they did because they were biologically programmed to do it. However, criticism quickly ensued (see Lehrman 1953). According to one criticism, it was impossible to estimate a priori how many instincts operated as determinants of behavior. It seemed that each new response pattern could be attributed to an unknown instinct. Another criticism was that there were no precise criteria to distinguish what

was an instinct and what was not. More importantly, because instincts were biologically fixed, they made behavior invariant instead of an evolved expression of adaptive actions (Strassmann 2014). In sum, appealing to instincts did not help much to address several issues about the causes of behavior.

The concept of a drive state had several advantages over the concept of an instinct. Although instincts and drives were supposed to have a physiological basis, this basis seemed easier to study experimentally for drives, as they were defined more clearly and precisely. Additionally, research indicated that biological correlates of drives could be more precisely measured. A remarkable attempt to do this was reported by Jenkins et al. (1926), who developed an apparatus to measure specific drives, and suggested that these measures should be distinguished from the measurement of general and random activity.

Experimental results using such measurements supported the characterization of a drive as a dynamic central state. During the first half of the twentieth century, it was broadly accepted that an increase in drive was associated with an increase in general activity (Dashiell 1925), provoked by an alteration of the organism's homeostasis. Richter (1927) reported that activity increased with biological needs. Therefore, drives did not specifically direct particular behaviors to satisfy the underlying need. Rather, the effects of a drive seemed to be broad and coarse. All these results led to a distinction between the exogenous stimulus that had the potential to provoke a response, and the subject's internal drive (see Pecoraro 2005).

American psychologists thus proposed the drive theory of motivation as an alternative to the instinct theory that dominated in European ethology. This alternative proposal was central to classical learning theories between 1930s and 1950s, primarily from Clark Hull and Kenneth Spence. Hull (1943) viewed drives as "typical intervening variables" (p. 57), symbolized as  $D$  in his famous (abridged) equation  ${}_SE_R = {}_SH_R \times D$ , where  ${}_SE_R$  denoted the reaction potential (probability of response  $R$  to stimulus  $S$ ) and  ${}_SH_R$  denoted the learning-dependent habit ( $S$ - $R$  associative) strength. Hull hypothesized that  $D$  was "produced" by a need (see "Need Reduction," this volume).

More specifically, Hull viewed the "hunger drive" as "primary" and a "function of *observable* antecedent conditions, i.e., of the need which is measured by the number of hours of food deprivation" (ibid.). Somewhat less abstractly, Seward (1956) viewed a drive as an "excitatory state produced by a homeostatic disturbance" (p. 195). This definition is largely consistent with the one used by Hull, Spence, and other classical learning theorists. However, talk of "drive state" is not commonly found in the works of these authors. It thus is unclear whether they would have made a conceptual distinction between drives and drive states. Perhaps, by "drive" they referred to a general *type* of condition, whereas "drive state" could be used to refer to a more specific condition (more on this distinction later on).

Still, the expression "drive state" makes it clear that a drive typically, if not always, is a *temporary condition* of an animal. Sometimes an animal is *in* a drive state, sometimes it is not (or it is but to a lesser degree). When *all* of an animal's needs are satisfied, the animal supposedly is not in any drive state (or it is to a small degree). The notion of a state as a temporary condition, of course, is widespread in all natural sciences, beginning with physics. For example, the notion is central to the concept of entropy, defined in terms of the number of a system's possible microstates. The essentially temporary character of a state makes being in a drive state *dynamic* in nature, which facilitates viewing all phenomena that involve drives as *processes* that can be mathematically described through differential (or, if time is viewed as discrete, difference) equations.

Hull's (1943) theory was partly inspired by Edward L. Thorndike's "Law of Effect." One of Thorndike's works (1932) cited by Hull provides the following formulation of the law as a "principle of connection-forming": "... what happens as an effect or consequence or accompaniment or close sequel to a situation response, works back upon the connection to strengthen or weaken it" (p. 6). Such talk of "connection" made Thorndike call his view "connectionism," which he submitted as a "new associationism" that "differs deeply and widely from that older British associationism" (p. 4). A key notion in this law was that "repetition

of a situation” played a key role in the formation and strengthening (or weakening) of situation-response connections.

Hull based his theory on a wide variety of experimental data. For example, one of his many laboratory assistants (Williams 1938) studied the effects of the number of reinforcements and food deprivation level on resistance to extinction (rate of response reduction upon discontinuation of reinforcement) of bar-pressing in rats in a Skinner box. The data showed that resistance to extinction increased as a negatively accelerated function of the number of reinforcements and a positively accelerated function of the number of hours of deprivation. The basic explanation in Hull’s theory is that the number of food deprivation hours increases  $D$  in a positively accelerated fashion, whereas the number of reinforcement increases  $sH_R$  in a negatively accelerated fashion. Both increases interact multiplicatively to produce a joint effect on resistance to extinction.

Hull viewed the presence of a drive, mathematically expressed as  $D > 0$ , as necessary for the behavioral expression of habits (i.e., for  $sE_R > 0$ ). Clearly, according to his equation, if  $D = 0$ , then  $sE_R = 0$ , for any value of  $sH_R$ . In this view, if there is no drive, there is no reaction potential either, even if there has been learning (i.e.,  $sH_R > 0$ ). According to Hull, if the animal has learned just the one habit,  $D > 0$  allowed for the behavioral expression of that habit. If the animal has learned several habits,  $D > 0$  evoked the strongest one.

Hull also distinguished between primary (or innate) and secondary (or learned) drives. Primary drives bear most directly and immediately on the organism’s biological survival. Although his research on maze learning focused almost entirely on hunger as a primary drive, he admitted other primary drives such as thirst, sex, and social interaction. Secondary drives, in contrast, are learned and do not directly bear on the animal’s biological survival, although they can certainly help the animal deal with environmental conditions that could eventually bear more directly and immediately on its survival. Learned drives became conceptually necessary to account for the persistence of behavior in the temporary absence of reinforcement. Related notions in learning research are second-order

reinforcers in Pavlovian conditioning and secondary reinforcers in operant conditioning.

After playing such a central role in theories of motivation and learning during the 1940s and 1950s, the concept of a drive state gave way to the concept of an incentive, an external stimulus that can create a need and *pull* (as opposed to the *pushing* effect of drives) the animal towards the stimulus. For example, someone could get hungry (or just come to want to eat) upon seeing food. Typically, incentive theories focus on situations where animals must behave in certain ways to obtain the incentive, which implies that they must be able to somehow anticipate the consequences of their behavior. However, this focus applies more clearly to instrumental than Pavlovian conditioning, where, strictly speaking, there is no explicit instrumental contingency or consequence of any behavior. Thus, it is most unclear how incentive theories can account for Pavlovian conditioning, unless the adventitious response-reinforcer relation that occurs during the maintenance of Pavlovian conditioning is postulated to “reinforce” that response in an “operant” way. Additionally, incentive theories still have to come up with plausible *mechanisms* that explain exactly how incentives affect the behavior that occurs to obtain them. If someone is told they will get \$5 (incentive stimulus) for whistling (required response), and then they whistle, how did the incentive make the whistling happen in the first place?

Despite these limitations, the concept of an incentive is thought to solve some difficulties with the drive-reduction hypothesis. For example, it is unclear exactly how secondary reinforcers such as lights and tones (or, in the more complex situation of a maze, contextual cues such as corners and walls) reduce drives. Perhaps such reinforcers function in a different way, other than changing drive states. But exactly what it is remains elusive for classical drive-reduction theories. Another difficulty is that animals quite often engage in behaviors that do not seem to lead in any obvious way to a change in a drive state. Behaviors such as seemingly spontaneous exploratory activity and pleasure-seeking (Brown 1955) do not seem to have a clear drive-reduction value.

Animals quite often eat just because they want to, not because they are hungry. And when hungry, animals often show preferences for certain kinds of foods over others, a phenomenon that becomes inexplicable under drive-reduction theories, insofar as, classical drive theory views all foods as equally effective to quench hunger.

Nowadays, despite the waning of the concept of a drive in the psychology of learning, strong interest remains in studying the effects of food or water deprivation, as well as other primary drives. For example, Stephens (1981) has studied the effects of food deprivation on risky choice. He observed that the level of food deprivation, relative to the subject's energetic requirements, determined the probability of choice of a constant but insufficient (nonrisky choice) over a variable but perhaps sufficient (risky choice) source of food. More recently, Kacelnik and colleagues (e.g., Pompilio et al. 2006) have studied the level of food deprivation on the value attributed to a response alternative in a choice task, a phenomenon they have called "state-dependent valuation learning." Their evidence suggests that food deprivation when an animal faces a response option for the first time increases the probability that the animal will choose that option when presented with another that delivers the same consequences.

There are plausible substitutes for the concept of a drive state and all the theories based on it. Learning, theorizing, or, as it has come to be more customarily and humbly known, "modeling," has made great advances. Recent models have risen to the occasion of explaining phenomena that are unexplainable in terms of changes in drive state. Among the most impressive phenomena, discovered after the golden age of drive learning theories, are blocking, latent inhibition, misbehavior, and autoshaping, just to name a few.

In blocking, previous Pavlovian conditioning of a conditioned stimulus (CS) A interferes with the conditioning if another CS X if both are paired in compound with the unconditioned stimulus (US). From the perspective of a drive theory of learning, it is unclear why conditioning to X is weak despite being paired with the US. Latent inhibition is a significant retardation of conditioning to X after X has been preexposed alone. Drive theories of

learning predict the opposite effect: The drive after preexposure should be higher (as there was no need satisfaction during the preexposure phase), for which acquisition should be faster.

Drive theories of learning face similar difficulties with other phenomena. Misbehavior is the occurrence of collateral, adjunctive behaviors that significantly delay instrumental reinforcement. Auto-shaping is the acquisition of an instrumental response (e.g., keypecking) through purely Pavlovian contingencies where a visual cue is paired with response-independent food. These last two phenomena have led to question traditional ways to understand the instrumental-Pavlovian distinction.

There also has been a proliferation of more sophisticated models that have incited much further empirical, theoretical, and conceptual work, which has promoted a healthy scientific competition that can only result in progress. The Rescorla-Wagner model (Rescorla and Wagner 1972), as impressive and numerous as its successes have been, also suffers from important failures. For instance, the model does not predict latent inhibition. As a result, many other models have been proposed, all of them with successes and failures. As part of this proliferation, some modeling efforts (e.g., Sutton and Barto 1981) have joined the connectionist revolution in psychology, a sort of revival (with important modifications, to be sure) of Thorndike's old connectionism. Contemporary connectionism (see Rumelhart et al. 1986) is better characterized, not as a school of thought, but as a cross-disciplinary movement that seeks to explain adaptive behavior in terms of artificial neural networks, abstract neural circuits where representations are distributed and processed in parallel. These models are inspired by brain structure and functioning, for which they are said to be "subsymbolic." Despite this subsymbolic character, or perhaps because of it, these models have been very successful in simulating many different kinds of complex adaptive behavior. Such success demonstrates that adaptive systems such as animals need not be conceived as symbolic to be successfully explained.

None of these models uses the concept of drive state and related concepts like need and motivation. This commonality suggests that it is

time to dispense with these concepts altogether, at least as traditionally defined in psychology. But perhaps there is no need to be so extreme. The possibility could be explored of redefining these concepts in thermodynamic terms, as suggested above, and see what results from this redefinition. A model formulated in this direction is the so-called “Boltzmann machine” (Hinton and Sejnowski 1986), an artificial neural-network with fully, symmetrically connected, stochastically activated units. This model is squarely framed within thermodynamics. The model also is subsymbolic, which proves the possibility of a nonsymbolic (noninformation-processing) thermodynamic model of adaptive behavior. However, it is unclear whether and how the types of phenomena that learning psychologists study, especially instrumental and Pavlovian conditioning, can be simulated with Boltzmann machines as we know them today. It might be possible to build a Boltzmann machine for these phenomena, and where the concepts of drive state, motivation, and need, suitably redefined, play a renewed role.

## Dual-Store Model

Russell A. Vogel

Stony Brook University, Stony Brook, New York, USA

### Definition

A model of memory proposed by Atkinson and Shiffrin (1968) that features memory as being comprised of three major components: sensory memory, short-term memory, and long-term memory. Also known as the Multistore Model of Memory.

### Introduction

In their proposal of the Dual-Store Model, Atkinson and Shiffrin (1968) claim that memory processing involves a series of sequential processes that lead to the input, storage and usage of information. This model of memory breaks down memory processing into three distinct components known as *sensory memory*, *short-term memory*, and *long-term memory*. Information is first processed in the form of sensory memory, and subsequent processing leads this information to be stored in short-term memory and later transferred to long-term memory.

## Sensory Memory

In the initial phase of memory processing, stimuli from the environment are detected via the senses and the information provided is stored in the form of *sensory memory*. The existence of such a form of memory is supported by studies in which participants were quickly shown a matrix of words on a machine that briefly displays images, known as a tachistoscope (Sperling 1960, 1963). Immediately after viewing the matrix of words, participants were asked to write down as many letters that they remember seeing, with the average number of letters remembered being six. Subsequent studies involved the presentation of a matrix of letters on a tachistoscope where after viewing the matrix, participants were told to report back the letters in a particular row (Averbach and Coriell 1961; Sperling 1960, 1963). Participants were able to correctly identify the letters in each particular row, indicating the existence of a complete, visual image that is briefly stored in memory.

Sensory memory is further broken down into two subcategories, with *iconic memory* being comprised of memories from the visual system and *echoic memory* being comprised of memories from the auditory system. The memories formed during this stage last only a very short duration and are forgotten or decay if not transferred into short-term memory soon after they are formed. While the senses detect a large quantity of information from the surrounding environment, only some of this information is paid attention to, a process known as *selective attention*. Through selective attention, information that is paid attention to in sensory memory is able to transfer on to short-term memory, while unattended information is forgotten.

## Short-Term Memory

Compared to sensory memory, short-term memory lasts for a somewhat longer duration, with memories lasting approximately 18–20 seconds. Short-term memory can hold approximately five to nine separate memories, with the average capacity of items being seven (Miller 1956).

While approximately five to nine separate memories can be stored in short-term memory, the amount of information stored can be increased through a process known as *chunking*, where multiple pieces of information can be grouped together into a single memory or “chunk.” An example of chunking includes remembering a telephone number, where a ten-digit phone number can be remembered as two chunks of three digits and one chunk of four digits (i.e., xxx-xxx-xxxx). Short-term memory consists of memories that are within one’s consciousness and is described by Atkinson and Shiffrin (1971) as “a store in which decisions are made, problems are solved, and information flow is directed” (p. 83), earning it the nickname of *working memory*.

Because of the short duration and low capacity of short-term memory, its memories can be forgotten or displaced by new information. In order to retain information in short-term memory, the memories that contain this information must be rehearsed. This process, known as *maintenance rehearsal*, helps keep memories in short-term memory and simultaneously prevents the information from being forgotten.

## Long-Term Memory

In order for information to transfer from short-term memory to long-term memory, a process known as *encoding* must occur. Though the use of simple repetition via maintenance rehearsal can lead to the encoding of memories in long-term memory, a more complex type of rehearsal process known as *elaborative rehearsal* is more effective. During elaborative rehearsal, memories in short-term memory are associated with information already stored in long-term memory. An example of elaborative rehearsal is the process involved in remembering a boat as a form of transportation and connecting “boat” to forms of transportation already in long-term memory, such as “car” and “plane.”

As a result of its creation of deep associations between short-term and long-term memory, information that undergoes elaborative rehearsal is more likely to be encoded into long-term memory

to the simpler techniques provided through maintenance rehearsal. Similar to the process of transferring memories from sensory memory to short-term memory, whether or not a memory is encoded in long-term memory also depends on the amount of attention placed on it; memories that are rehearsed for a greater amount of time are more likely to be encoded into long-term memory, while memories that are rehearsed to a lesser extent are forgotten. Long-term memory is the most stable of the components of the Dual-Store Model, with memories lasting in long-term memory from several minutes to a lifetime.

While memories in short-term memory are within one's conscious, memories in long-term memory are within one's unconscious and are not readily accessible. In order to access information from long-term memory, information must be brought back up to short-term memory through a process known as *retrieval*. There are two forms of retrieval, known as *recognition* and *recall*. Recognition involves the recognition of a cue, usually related to the memory, to trigger the retrieval of the memory. Recall involves the retrieval of information from long-term memory without the use of a cue, such as answering a free-response question. Because it does not have assistance from a cue, recall typically requires more effort to retrieve memories than recognition; this difference explains why multiple-choice questions on a test, which involve recognition, are usually easier to answer than fill-in-the-blank questions, which involve recall. Unlike short-term memory, long-term memory has no definite limit to its storage capacity, and the availability of memories from long-term memory depends on whether or not a memory can be accessed through retrieval.

Long-term memory can be further classified into two types of memory, known as explicit memory and implicit memory (Tulving 1972). *Explicit memory*, also known as declarative memory, is comprised of memories that are based off of information that can later be recalled. There are two types of explicit memory, known as semantic memory and episodic memory; semantic memory is comprised of memories based on facts such as the names of colors or the meaning of words, and

episodic memory is comprised of memories based on personal experiences such as remembering someone's appearance or what happened during an event. While explicit memory involves memories that are consciously recalled, *implicit memory* is comprised of memories of skills and procedures that can be learned and performed unconsciously, such as driving a car, riding a bike, or playing a musical instrument.

### Evidence of a Dual-Store Model

The existence of a Dual-Store Model of memory gained support through studies involving *free recall*, where an individual listens to an instructor read a list of words and is then asked to recall the items on the list in any order (Murdock 1962). When recalling a list of words, individuals tend to remember more words presented at the beginning of the list and at the end of the list, but forget words presented in the middle of the list. Words at the very beginning of the list are often remembered well because they are rehearsed the most, thus having more time to be encoded into long-term memory, a phenomenon known as the *primacy effect*. On the other hand, words at the end of the list are often remembered well because they are the most recently learned and are still in short-term memory, referred to as the *recency effect*. The words in the middle of the list are often forgotten because they are not encoded into long-term memory or are displaced by incoming new words into short-term memory. This group of phenomena, collectively referred to as the *serial positioning effect*, and the findings from studies involving free recall support the idea that memory is comprised of two distinct stores, with a short-term store for short-term memory and a long-term store for long-term memory.

The majority of free recall tests have individuals recall a list immediately after the items are read, known as an immediate free recall, but some studies have participants recall the list after a short duration of time has passed. This type of test, known as a delayed free recall, have participants complete a distractor task, such as a series of math problems, in between being read the word list and the recall period. Compared to immediate free recall, the number of words remembered from

the end of the list during delayed free recall tends to be lower (Glanzer and Cunitz 1966). This observation is due to the fact that newly acquired information during the distractor task displaces words from short-term memory, thus reducing the intensity of the recency effect by decreasing the amount of words available in short-term memory during the recall period. Experiments involving free recall have also determined that the format memories are stored in during short-term and long-term memory affect recall performance. Information in short- and long-term memory is typically stored, or *coded*, using one of three methods: auditory coding (by sound), visual coding (by appearance), or semantic coding (by meaning). However, information from any particular sense does not need to be stored in the same format that it is detected via the senses, such as a person remembering a conversation with another person by visualizing the words that they heard (Atkinson and Shiffrin 1968). Short-term memory is thought to prefer coding information acoustically, as immediate free recall performance has been better for groups of words that are phonetically similar, such as “play, clay, day.” Long-term memory, on the other hand, has been shown to prefer to code information semantically, as delayed free recall test performance has been shown to be better for groups of words with similar meanings, such as “large, tall, huge” (Conrad 1964; Baddeley 1966).

### Case Study of “H.M.”

In support of their Dual-Store Model, Atkinson and Shiffrin looked at a now iconic case study of brain damage involving man identified as “H.M.” (Milner 1959; Milner et al. 1968). Following a bicycle accident at a young age, H.M. developed epilepsy and suffered from regularly occurring seizures. In an attempt to treat H.M.’s epilepsy, doctors localized and surgically removed a majority of H.M.’s left and right medial temporal lobes, which included the hippocampi. Following the surgery, H.M. developed severe anterograde amnesia, meaning that he was unable to recall memories occurring after the surgery, as well as

mild retrograde amnesia, where he could not remember most events occurring 1–2 years prior to the surgery. H.M. was unable to store new information in explicit memory and could only remember events that occurred prior to 1953, the year that he had the surgery. While H.M. had impairments involving long-term memory following the surgery, his short-term memory remained intact, as he was able to perform tasks that involved recalling information stored in short-term memory. While “H.M.” was able to perform previously acquired skills, he was unable to remember recently taught information regardless of rehearsal.

The case of H.M. further suggests the separation of long-term and short-term memory processes and supports the idea that the processing and storage of the various types of short- and long-term memories are separate from one another.

### Baddeley’s Model of Working Memory

While Atkinson and Shiffrin’s concept of a Dual-Store Memory Model helped promote interest for research in memory processing, it received criticism from the scientific community. One of the largest areas of criticism for the model concerned how it suggests that information from sensory memory is stored and processed into short-term memory in the same manner for all of the senses. In contrast to Atkinson and Shiffrin’s idea of a singular store for all of short-term memory, Baddeley and Hitch created a model that features short-term memory being comprised of processes and storage areas specific for different types of sensory information, known today as *Baddeley’s Model of Working Memory* (Baddeley and Hitch 1974).

The original version of the model consisted of a “head” *central executive* system and two “slave” components, the *phonological loop* and the *visuo-spatial sketchpad*. The central executive is involved in problem solving and coordinates activity within the “slave” components through task switching, information retrieval, and selective attention. The phonological loop is

responsible for recording and processing information regarding auditory stimuli and is involved in the nonverbal rehearsal of how a word sounds and the order of words in a sentence. The visuospatial sketchpad is responsible for processing and storing visual stimuli and works by creating a mental image of what is seen. The separate processing and storage of auditory and visual memories prevents the phonological loop from interfering with the visuospatial sketchpad, allowing both components to work simultaneously without affecting each other's performance. Baddeley later revised the model to include a third component under the control of the central executive, known as the *episodic buffer*, which organizes multiple types of visual, auditory, verbal information into a chronological order (Baddeley 2000).

Evidence for such a model of working memory came from studies involving dual-task paradigms in which participants had to complete two tasks simultaneously (Baddeley Hitch 1976). The tasks involved in the dual-task paradigms were a digit span task, where participants did a digit span that involved repeating back a list of numbers, and a verbal reasoning task that involved answering True/False questions. As the number of digits to be remembered in the digit span task increased, the number of errors made on the verbal reasoning task remained unchanged. From this finding, Baddeley and Hitch concluded that participant performance was unhindered because the two tasks involved different forms of working memory, with the digit span task utilizing the phonological loop and the verbal reasoning task using the central executive system. Additional support for Baddeley and Hitch's model came from a case study of a man identified as "K.F." who suffered from impaired short-term memory due to brain damage resulting from a motorcycle accident (Shallice and Warrington 1974). K.F. had impairments in his verbal short-term memory yet intact visual short-term memory, indicating the existence of separate components involved in visual information (visuospatial sketchpad) and verbal information (phonological loop) in short-term memory.

In addition to the separation of short-term memory into separate components, the Baddeley

model also proposed the idea for separate stores for long-term memory. After being processed by one of the three "slave" components in short-term memory, information from each component is stored in a different form. Information from the phonological loop is stored in the form of language, while information from the visuospatial sketchpad is stored in the form of visual semantics and in the form of episodic memory for information from the episodic buffer.

### Separation of Long-Term Memory

Another part of the Dual-Store Model that received criticism was the methods that the model used to for coding memories during short- and long-term memory and the lack of the model's specialization for storage of different types of memories. Edmund Tulving (1972) stated that different types of information in long-term memory, such as procedural memory, semantic memory and episodic memory, are stored in different fashions through different types of encoding processes, rather than one universal method. An example of these principles can be seen through the case study of H.M. After undergoing surgery to treat his epilepsy, H.M. was regularly visited by a research team who taught him a mirror-drawing task, where one draws an image by looking at the reflection of their drawing, a task which becomes better with practice. While H.M. was able to retain his motor skills involved in the mirror-drawing task and subsequently began completing the task at faster speeds, he was unable to recall how or when he learned how to do the task (Milner 1965; Milner et al. 1968). In addition to his inability in remembering how he learned how to do the mirror-drawing task, H.M. was also unable to remember the meaning of vocabulary words. H.M.'s intact ability to encode and retrieve implicit, procedural memories from long-term memory despite having severe impairments in explicit memory suggests that different types of memories are stored and processed in different areas of the brain.

## Encoding Specificity

In addition to his comments on the Dual-Store Model's universal storage system for long-term memory, Tulving also suggested that there are additional factors that influence the effectiveness of memory retrieval rather than the format information is coded in (Tulving and Thomson 1973). According to Tulving, the retrieval of information is best when the conditions are similar to those during encoding, such as the context in which information was learned, the environment that something was learned in, as well as the mental and physical state that one is in when encoding and retrieving. An example of this is the idea that by studying for a test in the classroom that one will take the test, the scenario where the memories were encoded (during studying) will be the same as that during recall (while taking the test), thus allowing more memories to be recalled (Smith et al. 1978). This concept, known as the *encoding specificity principle*, states that contextual factors play a role in the effectiveness in memory retrieval more than the form that the memory is stored in.

## Levels of Processing Effect

Another model of memory that was developed as an alternative to Atkinson and Shiffrin's Dual-Store Model involved memory functions being based on the amount, or depth, of processing that is placed on pieces of information. This model, referred to as the *levels of processing effect*, claims that the processing of memories is divided into two categories known as shallow processing and deep processing (Craik and Lockhart 1972). Memories that undergo *shallow processing* are processed at the surface level using the senses, such as remembering a word by how it is pronounced, while memories that undergo *deep processing* are analyzed at a deeper, more elaborative level and are processed by the meaning behind it, such as the definition of a word. The strength of memories depends on the level of processing placed on them, with shallow processing

producing memories that are fragile and less memorable and deep processing producing memories that are stronger and more likely to be remembered over time. This model builds off of the concept already in place by the Dual-Store Model in terms of rehearsal methods, in which maintenance rehearsal helps temporarily retain information in short-term memory, while elaborative rehearsal leads to the encoding of information in long-term memory.

## Conclusion

The Dual-Store Model of memory helped pave the way to a better understanding of how the human memory system functions. While more complex models of memory have taken favor among the scientific community since its introduction, the Dual-Store Model promoted the idea that memories are contained in a short-term store and a long-term store. Atkinson and Shiffrin's Dual-Store Model led to an increased interest in memory research, leading to subsequent theories and developments on memory storage and processing.

## Duane Rumbaugh

David A. Washburn<sup>1,2</sup> and Duane M. Rumbaugh<sup>2</sup>

<sup>1</sup>Covenant College, Lookout Mountain, GA, USA

<sup>2</sup>Georgia State University, Atlanta, GA, USA

Duane M. Rumbaugh (July 4, 1929 – June 22, 2017) was an American comparative psychologist known for computer-based ape-language research with a chimpanzee named Lana, for developing the Transfer Index procedure for assessing intelligence across species, and for his conception of emergent forms of learning that reflect recognition of salient regularities in experience rather than stimulus-response conditioning. He served on the faculty of San Diego State College and of Georgia State University, where he chaired the psychology department and was the founding Director of the Language Research Center.

## Personal and Professional History

Duane Rumbaugh was born on the 4th of July, 1929, to Reverend Arthur and Ida (Traudt) Rumbaugh in the small rural town of Maynard, Iowa. Except for a brief period in the early 1930s in which the Rumbaughs (including two sisters born in 1919 and 1927) lived in the even smaller town of Alexandria, Nebraska, Duane spent the first two decades of life on and around the farms of Iowa. Growing up during the Great Depression in the Dust Bowl Midwest was hard, and Rumbaugh spent many hours tending to animals, haying, milking cows, and other farm activities, even as a youth. Too young for World War II, there was more than enough work to do back home, with so much of the workforce in the military. Strenuous farm jobs have motivated many bright young men and women to pursue higher education, and so it was that Rumbaugh headed to college after graduating as class President from Ackley High School in 1946, just a few months after the end of the war.

Duane studied psychology at the University of Dubuque, where he earned a baccalaureate degree

in 1950; however, he spent his entire senior year enrolled at the University of Iowa to strengthen his qualifications for graduate study. Duane was greatly influenced at Iowa both by the faculty from whom he took courses and also by some of his fellow students. It was on the recommendation of one such friend, a doctoral student named Anthony Cacioppo (who would himself have an accomplished career in engineering psychology), Rumbaugh enrolled in Kent State University to pursue a master's degree.

With the emerging conflict in Korea threatening military service, Duane was motivated to complete his thesis as quickly as possible. He worked under the direction of Charles C. Perkins, and was also influenced by Martin R. Baron and Raleigh M. Drake. All three had completed doctoral training at Iowa, two directed by Kenneth W. Spence and Drake supervised by Carl Seashore. Accordingly, it is unsurprising that Rumbaugh's thesis project was a maze study with rats, contrasting place learning with response learning. He received his M.A. in 1951, and continued his doctoral education with another former Spence student, Maurice P. Smith at the University of Colorado. Rumbaugh's 1955 dissertation was titled, *An Investigation of the Relationship Between Drive Intensity and the Growth of Habit Strength*, reflecting his theoretical orientation within the Hull-Spence framework.

Dr. Rumbaugh accepted a one-year Instructor position at San Diego State College (now University) in 1954, which became a tenure-track faculty appointment. Rumbaugh would remain at San Diego State until 1969, moving steadily through the academic ranks as an assistant, tenured associate, and professor. It was during this period that research in comparative psychology would begin in earnest, although the transition from general-experimental psychology to comparative studies was a product of good fortune at least as much as master plan. In early 1955, Dr. Rumbaugh met with his department chairperson to discuss teaching assignments. Flipping through the course catalog, Chairman Walcott Treat found one course that was not already "owned" by another faculty member: Comparative Psychology, which had not been

offered for some time. With his experience studying learning by rats and his background with farm animals, Dr. Rumbaugh jumped at the chance to be the department's resident comparative psychologist!

To obtain animals and laboratory facilities for this new interest, Rumbaugh approached the San Diego Zoo. Because of his experience, he gained access to rats and space to test them. The rats were from the breeding colony that provided food for the reptiles, but were otherwise fully available for learning research before being returned to the colony and the circle of life. Other animals, including pigeons, cats, chickens, and the occasional monkey, were also available in these early days.

With the Suez Crisis of 1956, Dr. Rumbaugh was again at risk of military service. He obtained a commission in the U. S. Naval Reserves as an officer in the medical service corps, and spent a summer in Bethesda, Maryland, at the Naval Medical Research Institute (now Center). He was assigned to work under the direction of Lt. Robert B. Voas on a project to determine whether a primate could survive flight aboard a Jupiter Intermediate Range Ballistic Missile – an important precursor to manned spaceflight. Dr. Voas (who would later become an astronaut training officer for the National Aeronautics and Space Administration's Mercury program) and Dr. Rumbaugh trained a squirrel monkey named Gordo for the 15-min suborbital missile flight, which launched in December, 1958. Biosensors indicated that the monkey tolerated the launch and flight with no ill effects; however, failure of the parachute system caused neither the monkey nor the missile to be recovered after crashing into the sea.

Dr. Rumbaugh returned to his academic position with renewed interest in nonhuman primates. He requested and was granted 90-sq. ft. of laboratory space where he could test apes and monkeys on discrimination-learning problems, in the fashion of Harry Harlow's classic learning set research. Among the animals that Rumbaugh attempted to test was the gorilla Albert, who expressed his displeasure with the situation by smashing the apparatus with his huge fist. Albert

was excused from further testing, but fortunately other animals were more willing to participate, and publications on primate (especially squirrel monkey) learning began to flow from the Rumbaugh laboratory.

Between 1963 and 1969, Dr. Rumbaugh held the administrative title of Associate Division Chairman, Life Sciences Division, San Diego State College. In 1969, he was recruited by Geoffrey Bourne, Director of the Yerkes Regional Primate Research Center at Emory University (Atlanta, GA, USA), into the position of Associate Director and Chief of Primate Behavior. In 1971, Dr. Rumbaugh left this position to join the faculty of nearby Georgia State University (Atlanta, GA, USA) as tenured professor and chairman of the psychology department. He chaired the department for 18 years, and remained on the faculty of Georgia State until his 2001 retirement as Regents' Professor of Psychology and Biology.

In his personal life, Duane Rumbaugh married twice. In 1952, he wed Phyllis Foresman, with whom he had a daughter. He subsequently married E. Sue Savage in 1976, and adopted her son. Duane and Sue Savage-Rumbaugh remain close collaborators long after their marriage ended.

## Significant Contributions

In a productive career that has spanned more than half a century, Duane Rumbaugh was a creative scholar, a visionary leader, and a skillful administrator. His many contributions to comparative psychology include several important innovations for methodology and theory. For example, his studies in San Diego suggested differences between species in the rate of two-choice discrimination learning; however, Rumbaugh recognized that there were many reasons other than intelligence itself that might contribute to performance differences. He developed the Transfer Index (TI) as a way to control for these other variables, producing an assessment of each animal's capacity to learn and to transfer learning to new situations. TI scores were found to vary systematically across primate species, with larger-brained primates

showing better transfer-of-learning and more rule-like relational (vs. associative) learning than the smaller-brained prosimians and monkeys (Rumbaugh and Washburn 2003).

Relational learning on the TI and its variations was cited by Rumbaugh as one example of what he termed "emergent" – a category of learning distinct from respondents (i.e., classical or Pavlovian conditioning) or operants (i.e., operant or instrumental conditioning). Emergents reflect the organism's perception of salient, rule-like regularities in experience (Rumbaugh 2002, 2013). They appear as complex and generalized competencies that have not been previously reinforced. Respondent, operant, and emergent behaviors constituted a framework that Rumbaugh called "rational behaviorism" to contrast with the radical behaviorism of B. F. Skinner and others.

Other examples of emergent competencies are found in language comprehension and production. When Geoffrey Bourne recruited Duane Rumbaugh to the Yerkes Center, he challenged Rumbaugh to study language learning by chimpanzees. Rumbaugh was hesitant, but finally capitulated, envisioning a fully automated language-training environment, in which apes could interact with a computer by means of a specially designed keyboard. Dr. Rumbaugh assembled a team of scientists and engineers, and the Language Analogue Project was born. One chimpanzee (Lana) and one orangutan (Biji) were selected for the study, but Lana's eagerness to engage the apparatus soon made her the focus of training. A vocabulary of visuographic symbols ("lexigrams") was developed, and each lexigram functioned as a word on the computerized keyboard. A grammar was also developed for the combination of these symbols, and Lana learned a variety of grammatical stock sentences that could be used to communicate with the computer and, more critically and effectively, with the human researchers who interacted with her. The work garnered considerable attention from the media and from scholars within the field, and was reported in numerous publications including 1977s *Language Learning by a Chimpanzee: The LANA Project*, edited by Duane Rumbaugh (1977). On the strength of Lana's impressive results, additional apes and special-

needs human children were subsequently trained to communicate with computer-based keyboards embossed with lexigram symbols.

The success of the ape-language work with Lana also led Dr. Rumbaugh, working with Sue Savage-Rumbaugh and other collaborators, to establish Georgia State University's Language Research Center (LRC). A series of laboratory and animal-housing buildings were constructed on more than 55 acres of forest, and the ape-language project was moved from the Yerkes Center to the LRC in 1981. Rumbaugh served as the LRC's first Director until his retirement in 2001, and oversaw expansion of the language-acquisition work to new chimpanzees (Sherman, Austin, Panzee) and a second ape species (bonobos, or *Pan paniscus*; Kanzi, Panbanisha); introduction of a language intervention project, headed by Dr. MaryAnn Ronski, in which children and young adults with intellectual disabilities were trained to use the keyboard-based language system that Rumbaugh had developed; expansion beyond language to studies of many other cognitive competencies, including numerical cognition, attention, memory, and cognitive control; and continuous support from the National Institute of Child Health and Human Development and other funding agencies.

Much of this cognitive work was facilitated by another methodological innovation. The introduction of the personal computer was rapidly changing the way human participants were tested in the late 1970s and early 1980s. After observing the chimpanzees elbowing Dr. Savage-Rumbaugh aside to gain access to a joystick and to respond to a computer game, Dr. Rumbaugh saw great possibilities for testing apes and even monkeys on game-like computerized tasks, and for using the test paradigm to provide environmental enrichment to support the psychological well-being of nonhuman primates. His publication of a hardware and software "computerized test system" that was used effectively with rhesus monkeys established a new testing paradigm that has revolutionized the comparative study of cognitive competencies (Rumbaugh et al. 1989).

For his many contributions – only a few discussed here – Duane Rumbaugh has been honored as a G. Stanley Hall lecturer by the American

Psychological Association (APA), as a Distinguished Professor by Georgia State University, with Outstanding Alumnus awards from Dubuque and Kent State, as Distinguished Member of the international honor society of psychology (Psi Chi), with the Donald O. Hebb Distinguished Contributions Award from APA Division 6 – Behavioral Neuroscience and Comparative Psychology, with the Lifetime Achievement Award from the Society for Experimental Psychology and Cognitive Science (APA Division 3), and with other recognitions. He has served as President of the Behavioral Neuroscience and Comparative Psychology Division of the APA, and of the Southern Society for Philosophy and Psychology.

## Dynamic Systems Theory

John P. Connell, Abigail DiMercurio and Daniela Corbetta  
University of Tennessee, Knoxville, TN, USA

### Definition

Dynamic systems is a theoretical framework that is used to understand and predict self-organizing phenomena in complex systems that are constantly changing, reorganizing, and progressing over time. Often mathematical formulae are used to capture processes of change within a given system.

### Introduction

The term “dynamic systems” is used to refer to a variety of phenomena in nonliving and living systems that display nonlinear behavioral changes over time. Behavioral change can occur in clouds formations in the sky or in a chemical reaction; it can reflect a sudden transition of gait pattern in a biological system, or a shift in flying pattern formation in a flock of birds. Dynamic systems aim to study the complex processes driving those changes. They are complex because whether occurring in a single system/organism, or a group of individuals, change occurs as the product of multileveled interactions between the various elements constituting these systems. Collectively, these dynamic interactions between elements of the system can lead to sudden transitions or the emergence of new forms in the behavior of the system. This encyclopedia entry provides a short history of the origins of this dynamic systems framework; it discusses its main tenets and

principles along with a number of examples focusing mainly on the behavior of biological systems.

## A Brief History

Dynamic systems theory originated in mathematics and physics. It is credited to Henri Poincaré (1854–1912) who developed the foundations of modern chaos theory, a precursor to dynamic systems. Chaos theory, and subsequently dynamic systems theory, began when Poincaré sought to understand the three-body problem. In this problem, he aimed to determine the final position of three celestial bodies, given an initial starting point and their relation to and effect upon one another. Several decades later, scientists found that the prevailing formulae of mathematics and physics, grounded in linear theory, did not explain the seemingly randomness associated with some experimental observations at the time. This randomness, initially considered as noise, was then seen as a crucial element that impacted the outcome of studies and observations. For example, Edward Lorenz (1917–2008), while working on weather forecasting, found an error that expressed the importance of taking “noise” into consideration when performing calculations or experiments. He found that minor differences in systems seemingly identical at their starting point, could result in two completely different systems given enough time.

The dynamic systems theory soon found applications to the fields of psychology and biology as a useful theoretical framework to capture and better understand behavioral change in living systems. To cite a few examples, dynamic systems theory has been used to capture transitions in movement coordination in humans and animals, such as fingers coordination (Schöner and Kelso 1988), gait transitions from walk to run in humans (Diedrich and Warren 1995), or trot to gallop in quadrupeds (Vilensky et al. 1991). It has been used in human development to comprehend how the seemingly erratic limb behaviors of newborn infants develop over time into functional behaviors such as reaching for objects and walking

(Thelen 1995). It has also been used to capture and model group dynamics such as the movement of crowds in public areas (Moussaïd et al. 2010), the complex interaction networks of ant colonies (Gordon 2010), or the thermoregulation of rat pups (Alberts 1978).

## Tenets of the Dynamic Systems Theory

### Multilevels and Multicausality in the Study of Change

The central quest of dynamic systems is to capture and understand how patterns evolve over time and transition from one mode of functioning (or state) to another. Often, pattern formation does not follow a predetermined, linear process. Biological systems, as many other systems, are complex and composed of a multitude of extremely varied elements inherent to the system corresponding to multiple levels (i.e., neural system, organs, functional characteristics, level of experience, energetic status, to cite a few) that continuously interact with each other in the most varied ways. Systems are also open to interactions with other elements that are external to the system (such as the physical environment, niche, group peers, social context, etc.). These interactions between elements from multiple levels of the systems can modify the elements themselves and their interactions, thereby altering the overall dynamics of the system’s behavior. Thus, change occurs as the product of these multiply interacting processes between multileveled elements.

This key tenet of the dynamic systems theory – that multiple, interacting processes can affect outcomes – is also referred by some as a multicausal process (Thelen and Smith 2006). The processes can be pressing on the individual from external sources present in the environment, but they can also stem from within the individual itself. For example, growth spurts in adolescence, weight gain, or drop in blood pressure can alter one’s physiology, mood, self-esteem, energy level, and so on. All these elements are connected and interact in time with the multiple levels of the system, entraining unique, sometimes unexpected changes in the system.

Good illustrations of multicausality in behavioral change come from infant studies. Before the introduction of dynamic systems to the field of developmental psychology, behavioral changes in infants were mainly viewed and studied independently of one another. Different behaviors within the infant system (i.e., perceptual development, body growth, reaching skill, walking, language, etc.) were assumed to follow independent developmental paths, and to grow as the product of a unicausal factor (often maturation of the central nervous system). There was little or no regard to the effect that each developing individual behavior had upon another. But infants are complex systems consisting of numerous subsystems, each developing at different rates, and studies in the last decades have shown how each newly emerging and existing subsystems can affect and can be affected by every other subsystem. This dynamic relationship between subsystems (or elements of the system) requires that the system be viewed as a whole organism with multicausal influences (not just one) driving developmental change. A first example of this was provided by the disappearing step reflex that was originally described in the early 1940s by Myrtle McGraw (1943). At the time, it was believed that the reflex was suppressed by neuromuscular maturation (a single causal factor). By applying a dynamic systems approach to this phenomenon, Thelen et al. (1984) discovered that other subsystems, in this case the rapid gain in weight and slower rate of leg strength of the infant, played a defining role in the suppression of the reflex.

Another well-documented example stems from Corbetta and Bojczyk (2002), who found that the emergence of bipedal walking (but also other forms of self-produced locomotion) can trigger temporary changes in reaching behavior. When infants produce their first independent steps, they have already developed fine reaching skills. They can use finger grasps for picking up cheerios, and they can anticipate grasping by shaping and orienting their hand ahead of contact with the object. Nonetheless, when they are beginning to walk upright, infants with extensive experience at reaching revert to two-handed reaching for

small objects while sitting – a behavior that is more typical of 4–6 months novice reachers. Corbetta and Bojczyk (2002) observed that during this critical period of motor learning, reaching, and walking, which have been typically considered as two functionally independent behavioral skills, in fact interact closely to allow the integration of the novel walking skill into the existing motor repertoire of the infants. When learning to walk, infants couple their upper arms intensely to maintain postural balance and generate steps. This upper arm coupling transfers to reaching, yielding this temporary return to two-handed reaching around walking onset. However, when infants become better walkers and do not need their arms so much anymore to maintain balance, the two-handed responses dissolve and infants show again more adapted reaching responses to objects in their environment. More recently, Corbetta et al. (2014) revealed that these walking-onset related changes did not uniquely incur in reaching, but affected cortical reorganizations as well. Thus, this example illustrates well how a change in the system (the emergence of walking) interacts with other multiple levels of the system (i.e., reaching, brain connections) to create a new form of behavior (the return to two-handed reaching). Extension of this work shows that this process is multicausal because walking is not the only behavioral form associated with an increase in two-handed reaching in the first year of life; scooting while sitting (Corbetta et al. 2006) and the onset of cruising onset (Atun-Einy et al. 2014) can lead to similar increases in bimanual reaching behavior, while other forms of self-produced locomotion such as belly crawling or hands-and-knees crawling are more linked to one-handed reaching responses.

Development is often thought to be an upward linear trend; however, it is a dynamic process that fluctuates with the different demands of the system. In many cases, development and behavioral formation unfold in a “seesaw” pattern, where the organism reaches periods of cost-effective functioning, alternating with periods of behavioral regressions, before continuing a trend of upward development. This has been seen in motor skills development as discussed above

(Corbetta and Bojczyk 2002; Corbetta et al. 2014), but occurs also in cognitive development such as in language development (Gershkoff-Stowe 2001). In language development, toddlers can begin to correctly map labels onto objects during their second year of life, and around 18–20 months old, they begin to go through a rapid period of productive vocabulary expansion. However, during this time of vocabulary expansion, the amount of labeling errors increases – production increases, yet children’s ability to accurately label words regresses. If this were to be a unicausal system, then the regression would be viewed as an unexplained decrease in the ability to produce object labels, or an overload of new words resulting in confusion and labeling errors. Gershkoff-Stowe (2001) supports that the system is more complex and dynamic; a child can correctly label a duck, yet when they are presented with a shoe immediately after, they label the shoe “duck.” This is an error in retrieval, not in the knowledge of the word. This is believed to be due to the child’s inability, at this stage, to overcome the priming effect and correctly produce the known label (Gershkoff-Stowe 2001). One of the major tenets in this example is the idea of coupling; language itself is a dynamic system with multiple processes linked together, or coupled. At this stage of development, retrieval and prior activation of the previously labeled word are tightly coupled such that the previously activated label interferes with the production of a new label. As the child continues to develop, there is a shift in the system where the dynamic between retrieval and prior activation is no longer tightly coupled, and therefore prior activation no longer interferes with accurate production.

The same principles of multicausality can be applied to the larger scale of group behavior, not just changes in behaviors of single individuals. For instance, in Zebrafish, shoal cohesion – the distance between neighbors in a group of fish – can be impacted by either aspects of their physical environment, social factors of the group, or both (Shelton et al. 2015). One factor of shoal cohesion is the density of the shoal (relative to the space available in the tank); however, shoal cohesion can also be modified by the social factor of

group size within the varying shoals. If the group size is different, but the density within the tank remains consistent, then there is no difference in the cohesion of the shoal; it is only when density and group size have a specific combination that there is an impact on the behavior of the shoal. If group cohesion were to be considered a result of a unicausal process, such as only the density in the tank, then the unique relationship between group size and density would not have been captured.

### **Self-Organization, Emergence of New Forms, and Nonlinearity**

How do systems transition from one mode of functioning (or state) to another? Given the intrinsic complexity of behavioral systems, with their large numbers of elements and interactions between elements, how do systems “know” how to reorganize? And how do they form stable patterns of functioning? Self-organization is the concept at core here. Systems evolve and move through discrete states (or behaviors) that form and dissolve continuously over time. These states can be stable or unstable depending on the interactions that are taking place between the elements in and/or out of the system. It is through the cooperation or assembly between these elements that states or behavioral patterns in the system emerge. However, given the intrinsic complexity of the systems, the formation of such new patterns or behaviors are often considered the product of self-organization or self-assembly. In complex systems, it is difficult to establish a hierarchy or order that dictates which element will entrain a change in the system’s behavior and how the ensuing interactions among elements will unfold. The changes occurring also cannot be considered as prescribed, preexisting, or preprogrammed. They are the direct product of the multileveled dynamic interactions occurring between elements of the system. For example, decades of studies in cognitive science have assumed that the brain was the ultimate organ receiving information, making decisions, and deploying responses, but from a dynamic systems perspective, the brain is only one piece of the complex process of making decisions and producing actions. The brain, the body,

the developmental history, the experience level of the system, and the existing constraints intrinsic to the system and the environment all partake in concert to the produced behavioral outcome of the system at a specific point in time (Chiel and Beer 1997).

Because of the patterns of interaction between elements and the way they self-assemble, systems are in perpetual state of change and transformation, and these transformations only exist as a function of time (this is certainly true for biological systems). Thus, behaviors are in constant evolution, second by second, minute by minute, creating new forms, dissolving those forms, reassuming old forms, or transitioning between forms. And often, these changes are nonlinear. Nonlinear changes typically reflect qualitative, sometimes sudden transitions in the behavior of the system, and again they result from modifications in the patterns of interaction between elements.

These concepts of self-organization, emergence of new forms, and nonlinearity can be best illustrated using crowd dynamics as an example. In humans, we are able to observe the spontaneous self-organization and emergence of new behavioral forms in pedestrian crowds. Pedestrian crowds illustrate the dynamic relationship that can exist between elements of a system (i.e., single pedestrian and/or grouped individuals). Similarly, to the shoal example described above, the size and density of the crowd are affected by the surrounding environment such that as the size of the crowd increases, the distance between elements decreases, and the members of the crowd also move slower. But large crowds were also found to be composed of 70% of its members belonging to smaller social groups within the crowd. These subgroups of pedestrians walk abreast to one another and are likewise affected by the environment. However, as the density of the overall crowd increases, it was found that the formation of the group changes into a “v-formation” around a central member in the crowd (Moussaïd et al. 2010). These changes are systematically arranged but not consciously decided. There is no central driving force that dictates the movements of all other members of

the crowd, but rather each individual, which is a system unto itself, interacts, affects, and is affected by the other surrounding individuals of the crowd. No one person expresses the need to change the group’s formation; it is an automatic reaction to the surrounding crowd’s density. This is a self-organizing system.

This is further illustrated when opposing flows of pedestrians meet on a walkway. When bidirectional streams of pedestrians meet, the two groups of pedestrians will narrow their overall size and pass one another on opposing sides rather than blending into one another. This turns out to be the most energy-efficient and effective way for the opposing streams to pass one another (Helbing et al. 2005). There is no “leader” in the two crowds of pedestrians or a specific protocol that dictates the actions of the groups; thus, the different crowds self-organize in a manner that most effectively circumnavigates one another.

More specific features of the environment can also be a significant factor in generating self-organization in systems’ behaviors. Research by Jeffrey Alberts (1978) countered the previously held view that rat pups were incapable of regulating their temperature, therefore deemed “helpless,” by examining group behavior while manipulating the ambient temperature. The goal of each pup, while forming huddles, is to reduce the amount of heat loss and the consumption of oxygen, thereby reducing metabolic use and saving energy. This is achieved by huddling into groups that dynamically interact in response to ambient temperatures. The surface area of the huddle expands and contracts in warmer and cooler temperatures, respectively. The composition of the huddle continuously changes, with pups cycling from the outer exposed surface area, a more metabolic costly area of the huddle, to inward toward the warmer, less costly inner portion of the huddle. Therefore, the huddled group temperature is self-regulated through the competitive actions of each individual pup as it moves to the warmer center of the huddle. Therefore, the rat pups share the costs of maintaining low metabolic expenditure. This example illustrates how a seemingly simple behavior such as rat pup huddling is actually a self-organizing

dynamic system that can only be truly understood when taking into account the different aspects and relationships that interact and produce the observed behavior.

### Attractor as a Metaphor for States and Transitions

Changes in patterns and self-organization create states that can be identified to describe the behaviors or patterns that are being produced by the system and its interacting elements at a given time. The word “attractor” is used to define these states in their given situations. In living organisms, observed and recurrent behaviors are called attractor states. These behaviors can be stable (this can refer to established forms of behavior such as walking or running in a human or animal) or unstable (meaning that the behavior is subject to imminent change). Transitions can occur when a current attractor state becomes unstable or is no longer viable, and the system as a result shifts to a more stable attractor. Transition in gait patterns is a classic illustration of such shifts from one behavioral state to another. Take the example of increasing speed in walking. As we walk increasingly faster, there is a point prior to the transition, where the state attractor – walking – becomes energetically costly, no longer efficient, and unstable. At this point, if we continue to increase speed, the system transitions to a more stable attractor state – running. This new state is more stable and energy efficient at the higher speed compared to the unstable state of walking at faster speeds. Such transitions are also frequently seen in the animal world, e.g., in horses, cats, dogs, and monkeys (Farley and Taylor 1991; Vilensky et al. 1991), where transitions to a new gait supersedes their previous gait that was no longer ideal for the amount of energy being spent. These changes are not only influenced by self-regulated actions, as walking speed in this example, but can also be affected by external forces from the environment. For example, walking against strong winds or walking over an iced surface will make running unstable and energy costly, pushing the system to adopt another locomotor pattern as a preferred one.

### Embedded Multiple Timescales and Developmental Trajectories

Most of the examples presented above corresponded to changes in behavior occurring within relatively short timescales. But what dynamic systems also brought to our understanding of change over time is that one change occurring in a system at a given moment in time (short timescale) can alter the broader developmental trajectory of the system over the more extended timescale (larger timescale). Biology, for instance, has already offered several examples of how, from initially identical conditions, organisms can form and develop quite different phenotypes depending on the system developmental history and interacting elements. Gottlieb (1992), as one example, has reported the case of two identical twins raised apart who developed to very different heights and body composition when they reached adulthood. It is easy to consider how factors such as diet, exercise, medical history, climate exposure, and probably many other environmental influences may have interacted with the genes to alter physical development.

Examples applying more specifically to behavior have been documented as well. For instance, in recent decades, it was discovered that the position in which a baby sleeps can alter the developmental timing of its subsequent motor milestones (Davis et al. 1998; Pin et al. 2007). Following the “Back-to-Sleep” campaign which was initiated in the 1980s in an attempt to reduce the rate of sudden infant death, it was noticed that the age at which infants began to perform a number of motor milestones, including crawling on hands-and-knees, was being delayed, and that in some cases, babies even skipped the crawling milestone altogether. Because infants were now sleeping on their back and side more often and for longer periods of time (than on their tummies), they were less enticed to use their arms and legs to push their body upward to be able to see their surroundings. Push-up behavior from laying prone was discovered to be an essential behavior to help babies transition to subsequent motor milestones and facilitate their discovery of crawling. As a result, pediatricians began recommending “tummy-time” during playtime to entice babies to push-up from a prone

position. This example illustrates how multiple timescales are embedded over time to alter the rate and form of developmental trajectories. As demonstrated here, a local change in the initial state (sleeping in supine or prone) can have extended cascading consequences for the development of future motor milestones.

Another example is stemming from animal behavior and the hatching behavior of domestic chicks (Casey and Martino 2000). This example also illustrates how a short timescale change introduced at an early stage of development can change the development of more protracted behaviors. When a chick hatches from their egg, they need to chip away the egg by kicking holes with their right foot 360 degrees, counter clockwise around the egg to emerge. After they hatch, if they are put in a T-maze where there is a forced choice of walking left or right, they overwhelmingly choose to turn left. They also display footedness preference of their right foot. The chicks appear to have a set laterality preference. In their study, Casey and Martino (2000) controlled the conditions of the nursery to maintain all conditions comparable to prior studies, but introduced unique modifications in the hatching behavior of the chicks. They manipulated the egg such that the chick only needed to peck around for a portion of the 360 degrees to hatch, thus reducing hatching behavior. When the chicks were tested later on, they found that the strength of their typical laterality preferences decreased significantly. Thus, again, the course of development, in this case laterality formation, was altered due to a shift in the hatching behavior performed earlier in life.

Embedded timescales are important in dynamic system theory as they illustrate how change occurring in the spans of seconds and minutes can impact the organization of the behavior over the span of hours, months, or years.

## Conclusion

Dynamic systems theory allows for the understanding of seemingly random nonlinear behavior and other phenomena observed in both living and nonliving systems. The basis of dynamic systems

theory is change – over time, through self-organization, within the individual, or in the environment. Just as the nonliving complex systems (i.e., chemical reactions, water currents, and weather forecasting) are affected by small changes, living organisms are also complex systems that are affected by the ever changing, self-organization, and reorganization of the subsystems that constitute them. Observed behavior of living organisms can more thoroughly be explained when viewed through the lens of the dynamics systems theory. As the systems within an individual reorganize, they can affect change in the behavior displayed by the individual, e.g., ambient temperatures influencing huddle formations (Alberts 1978) or the onset of walking creating a shift in reaching patterns exhibited by human infants (Corbetta and Bojczyk 2002). These reorganizations occur at multiple levels of the system (i.e., the development of infants language and motor skills), across different timescales (i.e., transitions in gaits over minutes and transitions in development over months and years), and are self-organizing (i.e., bird flocks and pedestrian crowds). Though dynamic systems theory originated in the fields of mathematics and physics, its applications in the area of animal and human research are invaluable.

## E.O. Wilson

Edward O. Wilson  
Museum of Comparative Zoology, Harvard  
University, Cambridge, MA, USA

Edward Osborne Wilson, Jr., born in Birmingham, Alabama, on June 10, 1929, grew up in many cities mostly within Alabama and Florida. He graduated with a B.S., M.S. (biology) from the University of Alabama in 1949, 1950 and a Ph.D. (biology) from Harvard University in 1955. He married Irene Kelley in 1955. Throughout his career he held multiple professorships at Harvard University, 1955–1997.

Many, perhaps most, children have a bug period during which they are fascinated by small living things. Wilson says he never grew out of his own bug period. At the age of 10, he decided that when he grew up he would be an entomologist. And he has never changed.

Butterflies were his first passion. Later, while living in Mobile, Alabama, his passion turned to ants. Close to his home, he found what proved to be the first colony of the imported fire ant (*Solenopsis invicta*) recorded in North America. He soon figured out that it belonged to a small population transported from Argentina or Paraguay to the docks of Mobile, Alabama, which were less than a mile from his family's house. From this site, the imported fire ant was destined to become a major pest across the southern United

States and thence onward to the West Indies, China, and Australia.

By 1942, the imported fire ant had spread widely through Lower Alabama and into Mississippi and the Florida Panhandle. Then a 19-year-old senior at the University of Alabama, and a dedicated myrmecologist (specialist on ants), and the world authority on the imported fire ant, Wilson was hired by the State of Alabama to study all aspects of the ant's biology and recommend a way to control it if possible. The result was his first scientific publication. He also found a new species of ant, the first of what was to be about 450 such novelties during his 70-year scientific career. He also became aware of a new kind of miniature beetle that rides on the backs of army ants, feeding on their oily secretions.

A year later, as a Ph.D. student of the University of Tennessee, he began to deepen his studies of the classification and natural history of ants in general, into what he was later to call sociobiology. Many species have multiple castes, beginning with the universal system of queen and workers (all female, incidentally) and extending to various combinations of soldiers, minors, supersoldiers, and intermediates. Tracing the most likely pathways of evolution leading to these arrays, he discovered that their origins can be mostly explained by changes in as few as two properties: allometry, the differences between the castes depending on size (e.g., big individuals have proportionately large heads), and the size frequency distributions. Both are colony-level

traits. It was immediately apparent that these traits arose by group selection, a process in time to become controversial.

In 1951, Wilson was invited to apply to the Ph.D. program in biology at Harvard. He enthusiastically accepted: Harvard had the largest collection of ants in the world, accumulated by the great myrmecologist William M. Wheeler. In 1953, he was elected to the Society of Fellows, which supported eight new scholars a year to go anywhere in the world and conduct research on any subject. There was only one requirement, which was read at the induction dinner: "Do something extraordinary."

And so, he submerged himself in the classification and biology of ants, traveling to Cuba, Mexico, New Caledonia, New Guinea, Australia, and Sri Lanka. He visited the major ant collections of the museums of Europe. All this travel was equivalent to Alabama writ large – very large. On settling back at Harvard, he married, worked hard, was appointed assistant professor in 1956 and given tenure in 1958.

The classification and biology of ants and other social insects were wide open at that time. In 1959, he and a few other researchers discovered the first glandular sources of pheromones in ant communication. Using ants and insects as models, he then worked with the mathematician William H. Bossert to create the first general account of physical and chemical properties of pheromones (1963). With Robert H. MacArthur, he made the data on ants acquired in the Pacific as an element of a theory of island biogeography (1963). This research eventually led many years later to Wilson proposing the Half-Earth project in global biodiversity conservation.

The pivotal event in the origin of sociobiology, however, occurred in January 1959. It occurred during a visit with Wilson's first Ph.D. student, Stuart Altmann (1930–2016), to the semi-wild rhesus macaque colony maintained on Cayo Santiago, an island off the coast of Puerto Rico. Altmann had chosen the social organization of this species for his thesis research.

Wilson was stunned by the complex patterns of dominance, alliances, leadership, and division of

labor he witnessed in each of the several groups present. In the several days he was on the island, insect and primate social organizations held their attention leading to the key questions: *What are the basic differences and similarities between the otherwise radically different species? And what principles about the origin and maturity of social behavior might they illustrate?* They saw that this body of research and knowledge could form a new discipline of biology. Altmann and he agreed that it should be called "sociobiology."

Through the 1960s, Wilson spoke often, both informally and at seminars, on the content of the new discipline. Toward the close of the decade, he decided to summarize the rich but still unorganized literature on the social insects that had accumulated during the past half century – primarily with social wasps, social bees, and termites. His idea was to make this widely scattered information available to students and researchers – and further, to use its generalizations to formulate as much as possible the principles of sociobiology.

His book, *The Insect Societies* (Harvard University Press, 1971), met these goals and formally introduced the discipline of sociobiology. It became the standard reference on the social insects, and was moreover a popular success, selected as a finalist for the National Book Award in 1972. For the first time, in addition he was able to connect sociobiology intellectually with other scientific disciplines (Fig. 1).

*The Insect Societies* also highlighted the genetic theory of inclusive fitness, introduced in 1964 by the British geneticist W. D. Hamilton. Based on earlier work by Ronald A. Fisher and J. B. S. Haldane, it posited that altruism in animal societies evolves when trade-offs made in personal sacrifice are more than compensated by benefits provided relatives. An individual may lose some of its genes in future altruistic behavior, but genes identified by common descent can be increased by its altruism, leading to a genetically based altruism among relatives. This attractive idea eventually faded away due to its flawed logic, among which is making the unit of natural selection the individual group member rather than the genes prescribing altruism. This approach has never

**E.O. Wilson, Fig. 1** The 1971 diagram of the connections that can be made between phylogenetic studies, ecology, and sociobiology, published in Wilson (1971)

worked in general population genetics, nor, as it turned out, can it be fitted to the origin of altruism.

*The Insect Societies* proved a considerable success in stimulating research theory on the social behavior of both animals and human beings. While lecturing on the subject at the University of California at Berkeley in the spring of 1972, Wilson decided to expand the synthesis to the organization

of vertebrate societies, as well as colonies of siphonophores and other primitive invertebrates, in other words all eukaryotic animals.

The result was the book *Sociobiology: The New Synthesis*, published by Harvard University Press in 1975. The work was intended to be encyclopedic – heavily illustrated, thoroughly documented, and complete in its coverage of the

scientific literature. It soon was recognized as the founding document of sociobiology as a scientific discipline, defined as “the systematic study of the biological basis of all forms of social behavior.”

*Sociobiology: The New Synthesis* succeeded. In 1975, however, a serious interruption occurred. With near unanimity, social scientists believed that humans lack instinct, and that instead all social behavior is culturally derived. Similarly, 1975 saw the end of the Vietnam War, and a widespread lingering belief among protest groups that any notion of a human instinct, entailing genetic causation, was intrinsically racist and pro-war. One of Wilson’s close colleagues at Harvard, Richard C. Lewontin, identifying himself as a devoted Marxist and “socialist biologist,” devoted his energies to discrediting the entire book *Sociobiology* as racist, and Wilson as an unintended purveyor of racism. There followed disruption of Wilson’s classes by angry students and mobs forming around Harvard calling for his dismissal. “Sociobiology” became, briefly, a political epithet.

What was labeled as the “controversy of the decade” in fact lasted only a year or two. In 1976, Wilson was awarded the US National Medal of Science for *Sociobiology* and his research programs that led to the book. In 1978, he followed *Sociobiology* with *On Human Nature*, which expanded on the full powers of sociobiology to help explain innate human behavior. This book was widely acclaimed, receiving the 1976 Pulitzer Prize for nonfiction. For *The Ants*, coauthored with Bert Hölldobler, and organized around the themes of sociobiology, he received a second Pulitzer Prize for nonfiction in 1991.

There is no question that *Sociobiology*, followed by *On Human Nature* played a definitive role in the rise of the discipline of evolutionary psychology, which was taking shape at the time. Some of its founders denied the influence, saying that evolutionary psychology sprang autonomously from independent novel combinations of evolutionary biology and psychology. A more convincing explanation is the desire by its authors in the late 1970s to avoid the stigma attached to sociobiology during the early turbulent years of its controversy.

## Ebbinghaus

Gustavo Munro<sup>1</sup>, Mario A. Laborda<sup>2</sup>, Gonzalo Miguez<sup>2</sup> and Vanetza E. Quezada-Scholz<sup>2</sup>

<sup>1</sup>Department of Psychology, University of Chile, Santiago, Chile

<sup>2</sup>Departamento de Psicología, Facultad de Ciencias Sociales, Universidad de Chile, Santiago, Chile

Hermann Ebbinghaus (1850–1909) is considered one of the experimental psychologist’s pioneers. He was one of the first to investigate memory using an experimental paradigm, heavily contrasting with the predominant unscientific approaches used by psychologists of his era. Despite the lack of proper control procedures in his work – relative to what we know today – he demonstrated that memory is a phenomenon that can be measured and studied scientifically.

## About His Life

Ebbinghaus was born on the 24th of January of 1850 in the former Kingdom of Prussia, specifically in the city of Barmen which belongs to the

province of Rhine. Son of a prestigious and wealthy merchant (Carl Ebbinghaus), he had a traditional evangelical education, and as soon as he was able, he joined the University of Bonn and later the University of Berlin and Halle (Shakow 1930). He studied history and philology at first, but quickly gained an interest in philosophy. Nonetheless, his studies were interrupted by the Franco-Prussian war in 1870, when he enlisted to serve his country at the age of 20.

Ebbinghaus resigned to the Prussian Army in 1871 and continued his studies in philosophy, obtaining his Ph.D. degree (1873) from the University of Bonn with a dissertation over the “Philosophy of the Unconsciousness” in a time in which he moved constantly between England and France taking the role of the teacher as well as the role of the student (1875–1878). During this period, he planned to return to Berlin and apply to an academic position, but this did not happen. Instead, he kept teaching as a tutor in England and France to finance himself. As an important side note in his life, in 1879 he became the French tutor of the young and ill Prince Waldemar of Prussia (Shakow 1930).

During his travels between London and Paris, Ebbinghaus acquired a book written by Gustav Fechner, which became one of his biggest inspirations. The book was titled *Elements of Psychophysics* (Fechner 1948), and its scientific approach to human behavior deeply moved Ebbinghaus to pursue a life researching the field of human memory (Shakow 1930; Roediger 1985). Specifically, Fechner’s book helped Ebbinghaus in designing a mathematical model for the study of memory and motivated him to follow the study of human behavior from an experimental point of view. Nonetheless, it must be noticed that the equations used by Ebbinghaus differ significantly from the ones used by Fechner (Roediger 1985).

Eventually, Ebbinghaus came back to the University of Berlin, wherein 1880 he founded the third laboratory of experimental psychology in history, after Wundt’s and Müller’s laboratories (Shakow 1930). During his time in Berlin, Ebbinghaus published one of his most significant works, titled “Memory: A contribution to experimental psychology” (Ebbinghaus 1913) where he

detailed his experiments and advances to the study of memory.

In 1894 Ebbinghaus was expecting to fill a vacant place as the head of the Department of Philosophy at Berlin and to become a full-time professor, nonetheless, most likely due to lack of publications, the promotion was given to Carl Stumpf instead. And as result, Theodor Lipps left his position at the University of Breslau – nowadays Warsaw, Poland – to replace Carl Stumpf in his former post at the University of Berlin. Due to the latter, and after receiving a formal invitation from the University of Breslau, Ebbinghaus left the University of Berlin and traveled there to fill the position left open by Theodor Lipps (Shakow 1930).

During 1894, his first year in Breslau, Ebbinghaus once again founded a laboratory for the experimental study of psychology and was invited to commission to study the decline of children’s mental ability during 5-h school sessions (Shakow 1930; Roediger 1985).

During his last years, Ebbinghaus published yet again some important books to psychology, *Fundamentals of Psychology* (1902) – *Grundzüge der Psychologie* – and *Psychology: An elementary text-book* (1908) – both books being a success for years even after Ebbinghaus death – (Shakow 1930). In these books, he presents a big part of his experimental works on memory. In his studies, Ebbinghaus tried to control the greatest number of variables that might be interfering with his observations, nonetheless, he was the only participant in most of his experiments, which in present days would not qualify as highly controlled studies.

Ebbinghaus died of pneumonia on February 26th of 1909. He was described as an ever caring and joyful person to his fellow students, presenting himself as always helpful and encouraging the diversity of opinions among his students (Shakow 1930). He was the father of Julius Ebbinghaus, who later became a well-known Ph.D. in Philosophy dedicated to studying the ideas of Immanuel Kant. Julius Ebbinghaus served his country during World War I and II, and during the latter, he also worked as a psychologist for the German army. After the war, Julius

Ebbinghaus occupied a high academic position as a philosopher for the University of Marburg (Herb 1989). Lastly, Julius Ebbinghaus's son, Ernst Albrecht Ebbinghaus did not get into philosophy or psychology as his father and grandfather did, instead, he dedicated his life to the study of American German's history, linguistics, and literature.

## About His Work

Ebbinghaus's memory experiments lacked external validity and the capability to generalize its results, mostly because Ebbinghaus himself was the only experimental participant of them. However, in an era where the scientific view of psychology was not the predominant stance of the discipline, he showed to the world that memory, a psychological process, could be studied with a scientific and experimental methodology (Murdock 1985).

Despite Ebbinghaus being interested in many topics like history, philology, and philosophy, and even given lectures on these topics, his main interest always was psychology and memory. In retrospect, he was one of the main scholars working to emancipate psychology from its philosophical roots and bring it to the scope and methodology of formal sciences.

Additionally, Dr. Ebbinghaus made a great service to the discipline by founding and editing along with Arthur König – a physicist and astronomer with interests in the color wave spectrum – the journal *The Psychology and Physiology of the Sense Organs* – *Zeitschrift für Psychologie und Physiologie des Sinnesorganes* – in 1890. The volumes of this journal were printed between 1890 and 1910 – until the moment of his death – representing an interesting portrait of the psychology of the change of century (Shakow 1930).

In its fifty volumes, we have a complete view and depiction of the psychology of two decades (Shakow 1930; Roediger 1985; Holling and Erdfelder 2007), especially because Ebbinghaus was very open to publishing the opinions of diverse groups into the journal. Thus, making it the most important psychological outlet in Germany, and consequently one of the most important

at the time in the entire world (Shakow 1930), considering it was the second psychology journal ever to be founded (Holling and Erdfelder 2007). Furthermore, it must be noted that when this journal was founded, German was the de facto language for scientific publications, which made it one of the main sources to publish empirical work in the field of psychology. It was the psychological analog of *Annale der Chemi* or *Annale der Physik* – both world-known media for scientific publications in chemistry and physics, respectively.

Such was Ebbinghaus's journal importance that the most influential works of Raymond Dodge, David Katz, Kurt Lewin, Hugo Münsterberg, and Charles Spearman were published in the journal. And more specifically, the pioneering and classical works of Schumann's and Lewy's early work on auditory, visual, and tactile short-term memories, Müller's and Schumann's classical experiments on episodic memory, Netschajeff's explorations of memory development in school children, Müller and Pilzecker's famous work on retroactive inhibition, Jost's laws on effects of relearning after different intervals, and Cohn's pioneering research on the detrimental effects of articulatory suppression on phonological short-term memory (Holling and Erdfelder 2007). Additionally, in contrast with the psychology of Ebbinghaus' times, the methodology and language in which he presented his work and in which the journal was written was one that resembles the writing of today's psychology and its methods (Roediger 1985).

Also, it can be noted that Ebbinghaus was a person who encouraged and engaged in discussion with different points of view related to psychology. He defended and promoted the scientific approach to the discipline, but he also encouraged others to have different opinions. Now, despite his gentle and caring personality to deal and discuss with people about psychology, and even considering his effort for the foundation of a couple of experimental laboratories in the universities where he taught, he never got really interested in the training of pupils who could continue his work after him. He was a magnificent teacher, but as a researcher, he never got interested in developing a

future legacy for his laboratory work (Shakow 1930).

Regarding Ebbinghaus's experimental work, it is easy to say that he will be especially remembered for his contribution to the forgetting curve, which is first described in his publication "Memory. A contribution to Experimental Psychology" (Ebbinghaus 1913). The forgetting curve describes the exponential loss of information while passing a certain amount of time. The decrease is exponential, and there are two sharp decline points in the curve, one occurs after 20 min (being the largest decline) and the second occurs an hour after learning a seriation list. After that, the curve stabilizes its decline following the first day (Postman 1968; Murdock 1985).

Specifically, the experiment consisted of learning and recalling many times, in the most complete way possible, a series of syllables until the sequence would be completely forgotten. These syllables or nonsense syllables were later put in a box from which sixteen were extracted, written down in a notebook, and then memorized for the experiment.

These syllables or combinations of nonsense syllables were used as a method of control and validity, because Ebbinghaus believed that by using proper words this could create an inference in the measurement of a proper recall due to words being associated with one another, thus facilitating the recall process. Additionally, Ebbinghaus noted that it seems that humans tend to look for words close enough to the nonsense syllable to make it more meaningful. Nonetheless, he did not go deeper into this topic (Roediger 1985).

The forgotten curve was mathematically modeled, explained by a logarithmic equation developed by Ebbinghaus. This fact made him one of the first psychologists to mathematically model his theory. Additionally, he reported that learning was more difficult after certain hours in the afternoon compared to the morning. This was an early indication of the influence of circadian cycles on memory. Furthermore, followed by the discoveries related to the forgetting curve, an interesting fact about learning was found. When Ebbinghaus attempted to review and restudy the sequence of syllables, he noted that the process of

relearning the same seriation task was faster than previous attempts (Roediger 1985). Now, the mathematical model of the forgetting curve was later picked and reviewed by Kjerstad in 1919. He disagreed with Ebbinghaus work, specifically due to lack of experimental subjects. But he used Dr. Ebbinghaus's findings to further develop the concept of learning curve (Kjerstad 1919).

In what regards to the learning curve, further development in the field of psychology is scarce, but some resemblance can be found in the error-correction expectancy of the model proposed by Rescorla and Wagner (1972) and the error-reduction present in the overtraining effect (Witnauer et al. 2014). Nonetheless, the concept was picked and popularized worldwide, especially in the field of production optimization, due to the work of Wright (1936) in the aviation industry, proposing a further development of the mathematical formula behind learning to calculate the cost of production. Additionally, the concept of a learning curve was also picked by machine learning to explain the performance increase due to experience in machines, with both terms being the least number of errors due to the increase in the number of trials, respectively (Newell and Rosenbloom 1981; Sammut and Webb 2010).

In addition to Ebbinghaus experimental work, the combination test he developed to measure children's intellectual fatigue was not very successful in comparison with the other test presented by the commission in which he worked when he was at Breslau in 1894 (Shakow 1930; Roediger 1985). Nonetheless it resulted very valuable to measure the general intellectual capacity by correlating the results with the scholarship level of the students, laying the ground for further research on this field, like the future development of the Healy Picture Completion Test and the Trabucce Sentence Completion Test (Shakow 1930).

It can be clearly said that compared to Wilhelm Wundt – who is recognized as the founder of the first formal experimental laboratory for psychology, and one of the main influences in the development of modern psychology as a science – Ebbinghaus was not an equal in matters of scientific publications, with a considerably smaller list of published works and without a systematic way

of publication. It seems that Ebbinghaus was contemptuous and satisfied with his studies and interpretation of memory. Nonetheless, it must be mentioned that he made his experiment with great care and careful methodology, he repeated his experiments on memory until he was sure to be satisfied with the results. His memory work was completed in 1880, but he did not publish it until 1885 (Ebbinghaus 1913), after repeating the experimental processes in its entirety (Shakow 1930).

Despite the criticisms that could be made to Ebbinghaus's work, especially related to certain aspects of his methodology (e.g., being himself the only participant of his studies), it has to be noted that his work remains relevant until today. His findings are robust, and despite not having a proper external validity, he pioneered many of the fundamental pillars of today's psychology (Murdock 1985; Postman 1968).

Finally, it is important to highlight that Ebbinghaus was a pioneer in the scientific study of psychology, and as many of his kind, he did his best to provide a proper and elaborated method of study and research with what he had. He may not be the one who established the bases of today's modern psychology, but he made the first steps towards that direction. He did not foresee many of the problems and methodological mistakes that we know today, but he remains an important landmark in an age in which psychology as we know it was still emerging, and in which a scientific and methodological approach to psychology was not popular or highly accepted (Postman 1968; Murdock 1985; Roediger 1985).

Dr. Hermann Ebbinghaus did not form a so-called school of psychology, nor a field of research (Shakow 1930). Nonetheless, the legacy of his work showed us something of great relevance to psychology. Is not the fact that he was the first to suggest the discovery of the forgetting curve. It is the fact that he showed us that complex organic functions of human beings, like memory, could be instrumentalized, subjected to a method, and thus granting us scientific knowledge of a process that was believed that it could only be discussed philosophically. His pioneering

incursion in the experimental study of memory set the bases of an upcoming trend in the rise of cognitive and behavioral sciences.

## Ebbinghaus Illusion

Audrey E. Parrish  
Department of Psychology, The Citadel,  
Charleston, SC, USA

### Synonyms

Ebbinghaus-Titchener illusion; Geometric illusion; Size illusion; Titchener circles

### Definition

The Ebbinghaus illusion is a geometric size illusion that emerges when two identically sized circles are misperceived on the basis of surrounding circles due to contrast effects. Larger surrounding circles lead to an underestimation of the central circle, whereas smaller surrounding circles lead to an overestimation of the central circle. The Ebbinghaus illusion, like many other visual illusions, has been used to assess similarities and differences in the perceptual systems of a wide range of species including humans, nonhuman primates, dolphins, dogs, birds, and fish.

### The Ebbinghaus Illusion

Geometric visual illusions emerge when the true physical properties of a stimulus (e.g., overall area, length, height, color, orientation, brightness) are misperceived on the basis of illusory-inducing features of surrounding stimuli. The Ebbinghaus illusion (Fig. 1), also referred to as the Ebbinghaus-Titchener illusion, is a classic geometric size illusion in which a central target circle (or dot) encircled by larger circles (or dots) is perceived as smaller than a central target dot of the same diameter encircled by smaller dots. Importantly, susceptibility to geometric illusions is contingent upon perceptual grouping mechanisms, in which the target stimulus (central dot) and its surrounding stimuli (outer dots) are assessed simultaneously. Geometric illusions have gained increasing popularity with comparative psychologists as a tool for investigating mechanisms of perception, including perceptual grouping.

### Ebbinghaus Illusion Studies with Humans

The Ebbinghaus illusion is one of the most well-studied and robust size illusions in the human literature. In the Ebbinghaus illusion and related arrays such as the Delboeuf illusion, contrast effects lead to overestimates in size if a target

**Ebbinghaus Illusion,**

**Fig. 1** The Ebbinghaus illusion. The gray central target dot in the array at left (encircled by larger surrounding dots) is perceived as smaller than the identically sized gray central target dot in the array at right (encircled by smaller surrounding dots)

stimulus is contrasted with smaller stimuli and underestimates in size if a target stimulus is contrasted with larger stimuli. Because size illusions emerge when stimuli are perceived within the context of surrounding stimuli (as opposed to when perceived in isolation), susceptibility to the Ebbinghaus often is discussed in light of perceptual processing mechanisms. As global processors, humans readily perceive multiple elements within a visual scene as a cohesive group prior to assessment of each individual element (i.e., perceiving the whole before the parts). For the Ebbinghaus array, this would mean that the central target dot is assessed in light of the surrounding dots.

Susceptibility to the Ebbinghaus illusion can be weakened or even diminished if grouping of the central target and surrounding dots is disrupted. For example, when the gap between the central target dot and the surrounding dots is increased, the illusion is weakened in human adults. The Ebbinghaus illusion also can be eliminated or weakened if the surrounding dots are diminished in any way so that they are less salient (e.g., decreased brightness, altered shape). Environmental or cultural influences on perceptual processing mode also have been examined using the Ebbinghaus illusion. In a cross-cultural study with human adults, researchers documented a decrease in the strength of the illusion among Himba tribesmen who are known to perceptually prioritize local elements versus global features (de Fockert et al. 2007). Thus, there is a direct relationship between susceptibility to the

Ebbinghaus illusion and perceptual grouping of the individual elements that comprise the array.

### Comparative Ebbinghaus Illusion Studies

In contrast to humans, who show fairly consistent Ebbinghaus illusion effects, comparative studies yield greater variability in perception of this size illusion among nonhuman species. Evidence suggests that damselfish, dolphins, domestic 4-day-old chicks, and redbellied splitfin also are susceptible to the Ebbinghaus illusion (*Chromis chromis*: Fuss and Schluessel 2017; *Tursiops truncatus*: Murayama et al. 2012; *Gallus gallus domesticus*: Rosa Salva et al. 2013; *Xenotoca eiseni*: Sovrano et al. 2015). Alternatively, evidence of either a reversed illusion (in the opposite direction of humans) or no illusory susceptibility (perception of the central target dots as equal despite the differing sizes of surrounding dots) has been documented in dogs, gray bamboo sharks, pigeons, domestic chickens, and baboons (*Canis familiaris*: Byosiére et al. 2017; *Chiloscyllium griseum*: Fuss and Schluessel 2017; *Columba livia*: Nakamura et al. 2008; *Gallus gallus domesticus*: Nakamura et al. 2014; *Papio papio*: Parron and Fagot 2007). The majority of these studies report individual differences with variability in illusory perception across animals (or species) tested under identical circumstances (e.g., Fuss and Schluessel 2017: damselfish vs. gray bamboo sharks). These

irregularities may emerge as a by-product of species-level differences in visual pathways (see Rosa Salva et al. 2013, for a discussion on mammalian vs. avian visual pathways) and perceptual processing mechanisms as well as differences in the methodologies used to test for susceptibility of the Ebbinghaus illusion.

Fundamental differences in species' ability to perceptually group stimuli may partially account for the variance in comparative results. Unlike most humans who are known to display a global-to-local precedence as discussed above, some species instead display a local-to-global precedence. This means that baboons, pigeons, and chickens, all of which are known to display a local precedence, may perceive a weaker or an even reversed Ebbinghaus due to an orientation toward local elements prior to perceptual grouping. Alternatively, evidence for the Ebbinghaus illusion in a human-like direction was documented in redbill splitfins (Sovrano et al. 2015) and a dolphin (Murayama et al. 2012), both of which have demonstrated a global precedence. Nakamura et al. (2008, 2014) proposed that rather than experiencing the Ebbinghaus illusion as a contrast illusion in the typical human fashion, locally oriented species may instead perceive a reversed Ebbinghaus illusion due to assimilation effects. Assimilation occurs when two items close in proximity or size are integrated together, which typically leads to overestimation of size. Concerning the Ebbinghaus illusion, locally oriented species may assimilate the central target dot of the display with the nearby surrounding circles, creating a reversed effect of the illusion.

The procedures used to test for the Ebbinghaus illusion also may lead to variability in its perception across studies. Because animals cannot simply be instructed to respond to central target dot size only (i.e., "choose the larger central dot"), they must be trained to do so. This is particularly important for size illusions with multiple stimuli as the animal must respond to the target alone rather than erroneously responding to the surrounding dots or even total area of the target plus surrounding dots. In the case of the Ebbinghaus array, researchers may present differently colored target and surrounding dots or gradually fade in the surrounding dots to train

animals to respond to the target dot alone. Or, the surrounding dots may be present during training as they appear in testing but positioned at a distance from the target dot. While isolating the target dot is vital during training, this may inadvertently bias a subject to ignore the surrounding dots even during the critical test phase. This would lead to either no illusory experience (if outer dots are ignored altogether) or a reversed illusion (if outer dots are assimilated with the central target dot). Evidence of the Ebbinghaus illusion was documented in redbill splitfins, damselfish, chicks, and a dolphin, in studies that presented the surrounding stimuli used in the test phase as part of the training phases (Murayama et al. 2012; Rosa Salva et al. 2013; Sovrano et al. 2015). In contrast to this, a gradual exposure technique in which the surrounding dots were gradually introduced led to either no illusion in pigeons and domestic chickens or a reversed illusion in baboons (Nakamura et al. 2008, 2014; Parron and Fagot 2007). A particularly interesting avenue for future research would be to use multiple techniques for training within the same subjects to isolate the role of methodology in illusory perception.

The method by which an animal makes a choice among stimuli in these tasks may impact the strength and direction of the Ebbinghaus illusion. As discussed by Sovrano et al. (2015), chickens and pigeons indicated their choice between target dots via pecks to the desired stimulus in Nakamura et al. (2008, 2014) (e.g., versus using a joystick-controlled cursor or touch screen). Pecking may shift focus to the local elements of the stimuli as it necessitates a closer viewing angle of the illusory arrays. As demonstrated in the human literature, participants perceived a reversed Ebbinghaus effect when viewing the stimuli from a close perspective (e.g., Oyama 1960). To control for this potential confound, Rosa Salva et al. (2013) introduced an observational-learning technique with 4-day-old chicks, in which these animals approached the stimuli from a distance to facilitate a further vantage point which may have aided the perceptual grouping of stimuli and subsequent perception of the Ebbinghaus illusion. Thus, differences in training, choice modality, and stimuli design

likely play an important role in the emergence and strength of visual illusions.

## Summary

The role of perceptual processing mode (grouping mechanisms), experimental procedures (training techniques, choice modality, stimuli design), and species' unique evolutionary histories all play a vital role in the perception of the Ebbinghaus illusion. A comparative approach has provided interesting insights about the nature of this illusion as it emerges in different species. Experimental work with more species and individuals across the lifespan will continue to shape our understanding of the mechanisms governing both perceptions and misperceptions of visual stimuli.

Introduction

Echolocation (biosonar) is a specialized behavior which allows animals to use echoes from self-produced sounds to assess their environment for the purposes of orientation and foraging.

The term echolocation was coined by Donald R. Griffin (1944) to describe how bats orient using the differences between acoustic signals they produce and the echoes of these signals they receive from objects in their paths. Echolocation resolved what had been known as “Spallanzani’s bat problem” (the fact that bats could fly around a completely dark room but owls could not), because it described how bats could ‘see with their ears’ (Griffin 1958; Au 1993). A polyphyletic group of species uses echolocation (Table 1), including most species of bats, all toothed whales (e.g., dolphins), some shrews and tenrecs, some birds, and even some blind humans (Fenton et al. 2017; Surlykke et al. 2014; Thomas et al. 2004). Although animals such as tiger moths, seals, and dormice have been proposed as echolocators, we lack convincing evidence that this is correct. Many animals vocalize as they move but by itself, this behavior does not demonstrate echolocation.

Most of what we know about echolocation comes from studies on captive bats and toothed

whales (Fig. 1). Experimental protocols generally involve observing animals deprived of other cues (visual, olfactory, tactile, passive acoustic) successfully orienting around obstacles or correctly identifying objects (e.g., Au 1993; Buchler 1976; Griffin 1958; Kellogg 1961). Captive studies are increasingly supplemented by studies of free-ranging animals (e.g., Surlykke and Kalko 2008; Simard et al. 2010). Several recently published reviews provide a great deal of information about echolocation (e.g., Fenton et al. 2017; Surlykke et al. 2014). There are interesting levels of convergence in the range of behaviors associated with echolocation (e.g., Au and Simmons 2007; Teeling 2009).

Signal Production

Echolocation signals are usually produced in the larynx or mouth (Table 1). Among the bats known as flying foxes (family Pteropodidae), a few species echolocate with tongue clicks, as do echolocating blind humans (Fenton and Simmons 2015). Laryngeally echolocating bats, as the name implies, produce their echolocation calls in their larynges (Veselka et al. 2010; Yovel et al. 2011). Echolocating birds produce their clicks in the syrinx (Suthers and Hector 1982, 1985), the

**Echolocation, Fig. 1** (a) An Atlantic spotted dolphin (*Stenella frontalis*), an example of a toothed whale with arrow indicating the location of the melon and nasal passages. (b) A big brown bat (*Eptesicus fuscus*). Photos by Peter Simard, taken under NMFS research permit no. 10038 (a) and M. Brock Fenton (b)

vocal organ of birds. However, toothed whales produce echolocation signals in their nasal passages, specifically with a pair of phonic lips (often referred to as the Monkey Lips Dorsal Bursae (MLDB) complexes (Cranford et al. 1997)). The sperm whale (*Physeter macrocephalus*) has a modified but similar sound production anatomy (Cranford et al. 1996). While the sound production mechanism is well understood in the toothed whales, bats, birds, and humans, there are few data about production of echolocation sounds by shrews and tenrecs.

In air, echolocation signals are broadcast through the open mouth (birds, shrews, some bats) or nostrils (other bats). In water, the similar acoustic impedance between environment and biological tissues has led to the evolution of a series of reflective structures (air sinuses and a concave frontal region of the skull). The directionalization of echolocation signals also is facilitated by the melon (Fig. 1), a fatty structure located anterior to the phonic lips channels from which sounds move forward and away from the animal (Au 1993).

## Signal Types

### Clicks

Most animals echolocate with clicks (Table 1) which provide detailed information about objects in the echolocators' paths (Bucher and Mitz 1980). Clicks are short in duration (e.g., 40–70  $\mu$ sec for bottlenose dolphins, *Tursiops truncatus* (Au 1993)), broadband (Figs. 2a and b, 3a and b, and 4d and e), and often cover a range of frequencies. In water, sounds travel about five times faster than they do in air, therefore all toothed whales use short duration signals to avoid pulse overlap (Au and Simmons 2007).

### Tonal Signals

Unlike clicks, tonal signals (Figs. 2c, 3c, and 4f) show structured changes in frequency over time. Tonal signals are commonly used by most laryngeally echolocating bats (Schnitzler and Kalko 2001). They range in duration from  $\sim$ 1 ms to  $>50$  ms. The tonal signals are usually frequency modulated (FM) signals and, in bandwidth, can be broad (tens of kHz) to narrowband (a few kHz) to constant frequency (CF – by definition, 0 kHz bandwidth). Most bats use search phase echolocation calls that are some combination of broad and narrowband components (Fenton and Simmons 2015). Some species in four families (Rhinolophidae – the horseshoe bats, Hipposideridae – the old world leaf-nosed bats, Rhinonycteridae – the trident bats, and a few Mormoopidae – the mustached bats) use signals dominated by CF components.

## Frequency

Among echolocators, peak frequencies (frequencies with maximum amplitude) of signals range from  $<5$  kHz to over 100 kHz (Fig. 4d–f). Higher frequency signals (shorter wavelengths) provide more details about targets (Fenton and Simmons 2015). Many species of laryngeally echolocating bats regularly add harmonics (overtones) to their signals (Bates and Simmons 2011). Although it is common to read about “ultrasonic” echolocation, ultrasonic is not synonymous

**Echolocation, Fig. 2** Spectrograms of (a) bottlenose dolphin echolocation (*Tursiops truncatus*, 1024 point resolution, sample rate 200 kHz), (b) black mastiff bat echolocation (*Molossus ater*, 1024 point resolution, sample rate 250 kHz, 15 kHz high-pass filter), (c) Mesoamerican moustached bat echolocation (*Pteronotus mesoamericanus*, 1024 point resolution, sample rate 375 kHz). with echolocation. Ultrasonic refers to sounds above the range of human hearing, theoretically those above 20 kHz (20 kilocycles per second)

although most adult humans cannot hear sounds above 10 kHz. The difficulty with the human-based definition is that what is ultrasonic to one

**Echolocation, Fig. 4** Waveforms (sound pressure) of single echolocation signals from (a) bottlenose dolphin (*Tursiops truncatus*, note that signal itself is indicated by arrow, and waveforms after are from echo reverberation), (b) black mastiff bat (*Molossus ater*), (c) Mesoamerican moustached bat (*Pteronotus mesoamericanus*). Energy spectra of single echolocation signals from (a) bottlenose

dolphin (note that plot is only of echolocation signal itself as indicated by arrow in (a), and that dolphin echolocation commonly has energy above 100 kHz (Au 1993)), (b) black mastiff bat, (c) Mesoamerican moustached bat. Sound files from Natalija Lace (a, d) and M. Brock Fenton (b, c, e, f)

individual might be quite audible to another. The bats that Spallanzani and later Griffin studied (Griffin 1958) used ultrasonic signals, accounting for their silent (to humans) flight. Many other bats use echolocation signals entirely audible to most humans. These signals have most acoustic energy down to 8 kHz. Many toothed whales have echolocation pulses that are largely ultrasonic; however, broadband echolocation signals often have considerable energy at frequencies audible to humans. At the other end of the spectrum are bats whose echolocation calls are dominated by energy at 212 kHz (*Cloeotis percivali*), and echolocation pulses of the porpoises and *Cephalorhynchus* dolphins whose echolocation clicks only contain energy above 100 kHz. However, high frequency sound by itself does not signify echolocation.

### Patterns of Pulse Production

Echolocating animals typically produce trains of pulses as they move through their environment

(Fig. 2) and adjust the timing (cadence) of the pulses in response to the distance between themselves and the target(s). Most echolocating animals separate the outgoing pulse and returning echo(es) in time in order to avoid overlap between the high-amplitude outgoing pulses and the low-amplitude incoming echoes. This results in the decreasing inter-pulse interval (and often pulse durations) observed in bats and toothed whales as they approach a target (Au 1993; Griffin et al. 1960). In engineering terms, most echolocators are low duty cycle because the signal is on for only a brief period in any time frame (short signals separated by long periods of silence; Fig. 2a and b). A few bats separate pulse and echo in frequency, using Doppler shifted echoes to exploit changes in frequency associated with relative movements of echolocator and prey (Schuller and Pollak 1976). These are high duty cycle echolocators because signals are on for longer periods of time in any time frame (Fig. 2c).

High duty cycle echolocators produce long signals separated by short intervals of silence.

The only high duty cycle echolocators described to date are species in the bat families Rhinolophidae, Hipposideridae, Rhinonycteridae, and a few species in the Mormoopidae. This approach to echolocation is associated with Doppler shift compensation behavior and distinctive echolocation calls. These bats also have an “acoustic fovea” in their cochlea (inner ears); consequently, their hearing is most sensitive at the frequencies dominated by Doppler shifted echoes (Schuller and Pollak 1976).

Bats adjust the durations and frequencies of their echolocation signals (e.g., Fig. 4). Griffin et al. (1960) described the feeding buzzes of echolocating closing with flying insect prey. In these situations, interpulse intervals range from around 200 ms when bats search for targets to 5 ms as they close with prey. Toothed whales can also adjust the frequency content of their echolocation signals (e.g., Houser et al. 2005).

### Pulse Production and Echo Reception

In terrestrial echolocators, echoes arrive at the auditory bullae via the ears (in mammals the pinnae). The faces of laryngeally echolocating bats are often specialized for sound transmission and/or echo reception (Fig. 4). Facial features such as noseleaves may affect the structure of the outgoing signal or the cone of transmission associated with the calls (e.g., Zhang and Mueller 2006). Echolocating toothed whales receive echoes through their lower mandibles which are filled with lipids like those found in the melons. In this way, echoes are transmitted to the auditory bullae.

The data used in echolocation are the differences between what the animal says (outgoing signal) and what it hears (received echo). These differences include information in time and frequency domains. The timing of the return echo encodes information on the distance from the object (i.e., the two-way travel time of sound), while the frequency spectra of the echo contains information on the composition of the object. For echolocation to work, the outgoing signal must be registered in the animal’s brain for future comparison with returning echo(es) (Au 1993).

### Advantages and Disadvantages of Echolocation

Echolocation allows animals to orient themselves and to detect objects when light is unpredictable or absent. This is obviously advantageous to any organisms with this capacity. For example, echolocation gives oilbirds and cave swiftlets access to underground nest sites (Brinklov et al. 2013). Many species of laryngeally echolocating bats not only gain access to dark roosts but also can hunt prey in situations where vision is unreliable. Furthermore, the echolocation calls of some bats echo strongly from some plants that bats pollinate (e.g., von Helversen and von Helversen 1999). Much of the aquatic environment has reduced light levels, and many species of toothed whales forage at depths below the maximum light penetration. However, echolocation can be costly. Both oilbirds and swiftlets stop echolocating when they emerge into lighted areas. In bats, evolutionary development evidence suggested that species of Pteropodidae lost an earlier capacity for laryngeal echolocation (Wang et al. 2017), implying that echolocation was an ancestral trait. This suggests a cost associated with echolocation. The question of whether echolocation or flight was ancestral in bats remains a point of active discussion (e.g., Gunnell and Simmons 2012; Simmons et al. 2008; Veselka et al. 2010).

Information leakage likely is a primary disadvantage of echolocation. Biologists use the echolocation signals of bats and toothed whales to monitor patterns of activity and distribution. In air and in water, some potential prey for bats and toothed whales have ears that detect echolocation signals and allow the prey to avoid echolocating predators. For example, mammal-eating “transient” killer whales (*Orcinus orca*) use echolocation sparingly in comparison to fish-eating “resident” communities of killer whales, which is thought to be a behavioral adaptation to the superior high-frequency hearing of the mammal prey (Barrett-Lennard et al. 1996). Eavesdropping on the echolocation of foraging echolocators could also be an effective way for animals to detect and exploit ephemeral concentrations of prey (e.g., Wang et al. 2016). This underscores

the reality that one animal's echolocation signals can and do serve in communication (e.g., Dechmann et al. 2009) and contribute to inter-individual learning (e.g., Page and Ryan 2006).

## Evolution of Echolocation

Arguably, echolocation allowed the ancestors of bats and toothed whales to detect and track prey in situations where vision was not dependable. In either case, echolocation opened a new adaptive zone for these animals. The ability to echolocate has evolved repeatedly among birds (two orders) and among mammals (at least five orders). Echolocation can permit access to food sources and shelters not readily accessible to animals mainly restricted to vision. Echolocation by blind people indicates that echolocation can develop facultatively. This also is suggested by the appearance of some level of echolocation in some pteropodid bats (Boonman et al. 2014).

Among living pteropodids, echolocation seems most developed in some species of *Rousettus*, while species in other genera show more rudimentary echolocation (Boonman et al. 2014). It is obvious that in *Rousettus aegyptiacus* at least, echolocation with tongue clicks is sophisticated and well developed. High duty cycle echolocation has evolved independently in two lineages of bats (Teeling 2009). These bats are very effective at detecting fluttering targets, perhaps increasing access to flying prey in cluttered habitats. Toothed whales are thought to be a monophyletic group, suggesting that echolocation evolved only once in this group, approximately 35 million years ago (Steeman et al. 2009).

As noted above, many species that are potential prey for echolocators have ears tuned to the frequencies predators use in echolocation. In this realm, we know most about the interactions between bats and their insect prey (e.g., ter Hofstede and Ratcliffe 2016; Cocoran et al. 2009; Roeder 1967). However, it is clear that marine mammals (e.g., seals) can hear the echolocation of their killer whale predators (Barrett-Lennard et al., 1996) and the same abilities are

shared by at least some fish (e.g., Mann et al. 1997).

## Conclusion

As Donald R. Griffin noted, echolocation is one of the most significant modern discoveries about animal behavior. Echolocation has allowed certain animals to occupy spatial and temporal niches unavailable to those without the ability, and the sophisticated echolocation abilities of the bats and toothed whales has likely led to the ubiquity and diversification of these groups.

 Ethos, laboratoire d'éthologie animale et  
 humaine, Rennes, France

## Synonyms

[Hatching](#); [Spawning](#)

## Definition

Eclosion is the act of emerging from the egg.

## Introduction

Oviparity is by far the widest way for an individual to brood in animal kingdom; with some exceptions, invertebrates, lower vertebrates (amphibians, reptiles, fish), and birds are oviparous. From a cognitive standpoint, embryos in eggs are generally much more exposed to external sensory information than in viviparous species, the embryos of which receive buffered inputs through their mother. To adequately respond to environmental pressure at hatching (relevant abiotic conditions, finding food, and avoiding predators), siblings of oviparous species have three sources of information: (1) from their mother (from egg formation to incubation and hatching),

(2) from their own prenatal sensory experience, and (3) from their own perception of surroundings at eclosion. In addition, direct parental guidance in the peri-hatching period would enhance the development of cognitive skills in numerous oviparous species.

## Parent Effects on Hatchlings' Behavior

Parents have direct influence on neonates' cognitive architecture through genes. There is an extensive literature showing that behavioral response of the young to external stimuli depends on the species history. Some sensory inputs make sense to hatchlings, without previous sensorimotor experience; this can be considered, in cognitive ethology, as an “innate representation.” Sea turtles follow visual signals for sea-finding at hatching, ducklings will recognize mother call, even when devocalized and coming from eggs kept in artificial incubators (Gottlieb 1980). Influences of parents are also epigenetic; they can choose and arrange the laying site in response to their own knowledge of the environment. In many species, it is likely that location of egg mass or building-nest may be chosen carefully in safe sites (e.g., in Siberian jay, Eggers et al. 2006) where food is available for neonates and that adaptive social interactions are possible. These processes occur basically in all oviparous species in which the females lay their eggs in the site where they hatched themselves (eel, salmon, turtles, etc.) or resembling those they come from (e.g., ant queens with odor cues). Adaptive behaviors of hatchlings can also be influenced by information provided by mothers via the hormones deposited in the egg. For example, stressed mother of some birds and fish can produce yolk with modified concentrations of sex steroid hormones and cortocosteroids (e.g., in birds, for a review see Henriksen et al. 2011). These compounds will alter learning/memory skills of hatchlings and potentially their behavioral profiles. These parental investments to siblings are part of “parental effects” together with “parental care” *per se*. These post-mating parental cares are present from insects to birds.

Direct parental influence on embryo's perception of environment may also occur in case of egg attendance, nest building or burrowing, egg brooding, or ovoviviparity (see Royle et al. 2012, chapters 1, 4, and 5 for reviews).

### Embryonic Experience, Hatchlings Behavior and Cognition

As embryos develop in their egg, they get more and more information from their surrounding environment whatever the opacity of the egg capsule. Indeed, in vertebrates and in some invertebrates, the onset of sensory functioning follows an invariant sequence, the visual system being the last to develop. Given the relatively buffered nature of the prenatal environment, it is likely that the developing embryo is primarily exposed to unimodal stimulation and has relatively fewer opportunities to experience multimodal stimulation. Several studies showed that embryos react to these stimuli by reducing or increasing their heart-rate or ventilation. Such exposure can have profound effects on behaviors at hatching, in the feeding, social or defensive realms. Direct embryonic exposure to a chemosensory stimulus, or through the maternal diet, alters subsequent chemosensory preferences in favor of the familiar stimulus after hatching (e.g., in mite: Quesada and Schausberger 2012). When eggs of ringed salamanders (*Ambystoma annulatum*) were exposed to chemical cues from predators, post-hatching larvae showed reduced activity and greater shelter-seeking behavior (Mathis et al. 2008). Prenatal auditory learning also has been reported in birds. As mentioned before, ducklings will prefer their mother's calls when they have heard them as embryos; this learning will drive the duck's social preferences. In the superb fairy wren (*Malarus cyaneus*), embryos will learn the incubation call produced by their mother. After hatching this begging call will serve for nestling discrimination by the female and hence detection of intruder nestling, in this species parasitized by cuckoos (Colombelli-Negrel et al. 2012). In the cuttlefish, *Sepia officinalis*, juveniles that have

been showed crabs before hatching will alter their innate shrimp preference for a crab preference (Darmaillacq et al. 2008); this is the only evidence of prenatal visual learning. Besides exposure learning, embryos are also capable of other simple learning like habituation or association learning. Fairy wren embryos are able to learn to discriminate between the vocalizations of conspecifics and to habituate to a familiar call (Colombelli-Negrel et al. 2014). Wood frog embryos can learn to recognize unfamiliar predators by associating the odor of the predator with a conspecific alarm cue (Mathis et al. 2008). This recognition of the familiar stimulus could lead to a number of behavioral adaptations, such as modifications of habitat choice at settlement or of prey preference depending on the abundance of food. These factors could affect development and behavior in postembryonic individuals, all of which may increase their chance of survival.

In several oviparous species, from mollusks to birds, the peri-hatching period is a sensitive window during which individuals can learn and store a great amount of information that will serve in subsequent behaviors. Studies of these widespread and trans-specific processes have been one of the roots of modern ethology through the detailed description of imprinting in precocial birds and basic questionings about its biological significance (Immelmann 1975). Interestingly, associative structures of the brain are particularly immature at hatching. Since long-term memory is based on the capacity of the nervous system to be plastic, it is likely that neural plasticity of developing brain in hatchlings could allow easier recording and storage of information.

### Is Eclosion a Cognitive Disruption?

At the behavioral level, the question of continuity-discontinuity of hatching has been extensively debated in Ethology, at least in bird models. Factually, in most oviparous species, emerging from an egg corresponds to the appearance of specific motor patterns (which are more or less transformations of embryonic spontaneous

motility). From a sensory standpoint, hatching potentially provides the young animal with a big flow of new information (i.e., visual information in birds and many amphibians and fishes), potential disappearance of chemical inputs from the embryo's perivitelline fluid/yolk, and substantial changes in auditory and proprioceptive information. This is especially important in precocious species, the sensory systems of which are mature very early in life. However, both pre- and post-hatching information from the environment will be combined and processed by hatchlings to orient their early behaviors: respond to potential threats, recognize available food items, and interact with social partners. As a consequence, even if eclosion implies a severe sensory-motor discontinuity in sensory ecology of the organism, embryonic learning and memory of egg-surroundings will familiarize and prepare hatchlings to their post-embryonic environment. Cognition in embryo will help the newly hatched organisms to adaptively respond to their behavioral needs. To conclude, perinatal memory, if any, enables the young to mentally bridge the prenatal and the postnatal environments and hence ensures a perceptive continuum through eclosion.

|-------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Adaptive                | A trait that increases fitness is adaptive.                                                                                                                                                                                                                                          |
| Behavioral machinery    | Causes the immediate behavior. Typically the central nervous system (brain) reacting to specific stimuli by producing the observed behavior.                                                                                                                                         |
| Ecology                 | The science studying the interactions between and among organisms and their environment.                                                                                                                                                                                             |
| Environment             | All biotic and abiotic factors surrounding an organism, including individuals of the same species (social environment), other species, habitat, and weather.                                                                                                                         |
| Evolution               | Change of the heritable characteristics of a population or species over time.                                                                                                                                                                                                        |
| Fitness (evolutionary)  | This is a relative measure of reproductive success. Individuals with a high reproductive success have a higher fitness than individuals with a low reproductive success. If this difference in reproductive success is due to genetic differences, then this will lead to evolution. |
| Function (evolutionary) | Describes how a trait leads to an increase of fitness via natural or sexual selection.                                                                                                                                                                                               |
| Ontogeny                | Individual development from the fertilized egg over the                                                                                                                                                                                                                              |

|           |                                                                                                         |
|-----------|---------------------------------------------------------------------------------------------------------|
|           | juvenile stage, adolescence, and adulthood until senescence and death.                                  |
| Phylogeny | Evolutionary history, typically shown as a tree of life.                                                |
| Proximate | The mechanisms that cause a trait such as behavior. It refers to ontogeny and the behavioral machinery. |
| Ultimate  | Refers to the evolution of a trait, i.e., how and why it evolved (function and phylogeny).              |

Introduction

Ecology is a relatively recent science in biology. The idea that everything in nature is connected with each other was first emphasized by the German naturalist Alexander von Humboldt, in his *Naturgemälde* from 1807, showing both the biotic and abiotic aspects of the South America volcano Chimborazo. Throughout his published books, von Humboldt emphasized the complexity of nature and that species can only be understood if one considers their natural environment with all possible interactions with other species and climate (von Humboldt 1845–1862). In 1842, the then 73-year-old von Humboldt met the 32 years young Charles Darwin in England. Unfortunately von Humboldt was talking so much that it was impossible for Darwin to explain him his ideas about evolution (Wulf 2016). Nevertheless, the work of von Humboldt significantly influenced Charles Darwin as he was developing the modern theory of evolution. But even though both scholars realized how important interactions of individuals with their environment were, it was only in 1866 when the German scientist Ernst Hackel (an admirer of both von Humboldt and Darwin) used the word *Oecologie* for the first time to name the science of the interactions among organisms and their environment (Hackel 1866). The word *Oecologie* comes from Greek οἶκος, “house”, or “environment”, and -λογία, “study of,” and is translated in English as ecology. Interestingly, Hackel also invented the terms ontogeny and phylogeny, which later became

very important in animal behavior, as outlined below.

Ecologists study the influence of the environment on the individual, but environment and ecology are not perfect synonyms. Ecology refers to interactions in the natural environment, but the environment can also be artificial. Thus, in biology one typically differentiates between field studies in natural environment and studies in the laboratory under artificial conditions. However, laboratory experiments can also be used in ecology to test the effect of specific aspects of the environment on a trait. In ecology, one differentiates between aspects of the nonliving or abiotic environment and aspects of the living or biotic environment. The soil and weather (temperature, rainfall, etc.) are typical factors of the abiotic environment and other plants and animals of the biotic environment. All these environmental factors can also influence behavior. For behavior, the social environment (part of the biotic environment) can be especially important, i.e., individuals of the same species that live together in the same group or the same area.

### The Four Questions of Tinbergen and Ecology

In the field of animal behavior, first studies were often done in zoos, then with free-ranging tame animals under seminatural conditions, for example, by Konrad Lorenz during the 1930s and 1940s. At the same time, his Dutch colleague Nikolaas Tinbergen, who together with Lorenz got the Noble Prize for medicine in 1973, studied animals in their natural environment, testing often experimentally the influence of specific stimuli of the environment on behavior. Extensive field studies started in the 1950s and 1960s, leading in the 1970s to the establishment of behavioral ecology, for example, by E.O. Wilson (1975), and many field studies continue today (Schradin and Hayes 2017).

While the field of behavioral ecology always had a strong focus on the evolutionary function of behavior but neglected the proximate mechanisms of behavior, ecology plays an important role both

for ultimate function and proximate mechanisms. This was already made clear by Tinbergen, who formulated in 1963 four questions that form the basis of research in animal behavior (Tinbergen 1963) (Fig. 1). After Tinbergen, to fully understand behavior, one has to address questions about (1) ontogeny, the question about individual development; (2) causation, the question about the behavioral machinery causing behavior, i.e., normally the central nervous system; (3) function, the question about the fitness consequences of behavior; and (4) phylogeny, the question about the evolutionary history of behavior.

The questions about ontogeny and the behavioral machinery of behavior refer to the proximate mechanisms of behavior, while the questions about the phylogeny and function address the ultimate consequences of behavior. Importantly, the environment does not only influence the ultimate function of behavior but also its proximate mechanisms (Fig. 1). As such, the question of how ecology influences behavior and cognition can best be addressed by asking the four questions of Tinbergen and what the role of ecology is in finding answers to these questions. Hereby it is useful to first differentiate the influence of abiotic and biotic factors. Especially for social behavior, one also has to take the social environment into consideration. Addressing in this way the role of ecology for all four questions helps to understand the interplay of these factors and leads to the insight from von Humboldt that everything in nature is connected with each other.

### Ecology and Function

Behavior represents an evolved trait which has a heritable and genetic basis. For example, the deer mouse *Peromyscus maniculatus* is closely related to the oldfield mouse *Peromyscus polionotus*, but both species differ in social behavior. While males of the deer mouse mate polygynously with several females, males of the oldfield mouse live monogamously. Only males of the monogamous oldfield mouse but not of the polygynous deer mouse show high levels of paternal care. These differences in paternal care are heritable, and 12 regions in the

# Integrative Understanding of Behavior

**Ecology, Fig. 1** Integration of the four questions of Tinbergen to come to a comprehensive understanding of behavior and the role of the environment. We describe and measure behavior (black box on the right). Behavior is caused by the CNS (central nervous system = behavioral machinery) which developed during ontogeny in an individual specific manner. The behavior itself has fitness consequences (function) which changes the gene pool (genes and gene controlling DNA that regulates gene expression) of future generations (phylogeny). The gene pool determines potential genotypes of individuals. The

genotype and the environment determine the development of an individual (ontogeny) including its behavioral machinery. The environment (underlined) plays a critical role for all four questions: stimuli of the actual environment cause the behavioral machinery to express the observed behavior (causation); its fitness consequences depend on the recent environment in which the behavior is shown (function); it evolved in the environment of the ancestor (phylogeny); and it develops as gene-environment interaction (ontogeny).

genome have been identified that affect paternal care (Bendesky et al. 2017). Whether these heritable differences are due to the species having different genes, or whether there are species differences in gene activation, is unknown. Therefore, a modern definition of genetic differences includes all heritable differences, whether these are due to different genes or differences in gene activation. The burrowing behavior of the two species also differs,

leading to different forms of tunnel systems, and these differences are also genetically determined (Hu and Hoekstra 2017). Thus, behavior including social behavior has a genetic basis and represents traits evolved by natural selection that changes the gene pool of populations.

Whether a behavioral trait spreads in a population depends on its fitness consequences. Individuals that have a higher reproductive success have

a higher evolutionary fitness. If their reproductive success increases due to a specific behavior, then the genetic basis of this behavior will spread in the population. In the last decades, the main question in behavioral ecology was: what are the fitness consequences of a specific behavior?

The fitness consequences of a trait depend on the environment! For example, in many small mammals, basking in the sun to passively warm up is an important behavioral strategy to reduce energy consumption, which is believed to have fitness benefits (Scantlebury et al. 2010). African striped mice (*Rhabdomys pumilio*) live in the Succulent Karoo semidesert of South Africa, where food availability is low during the dry season. Accordingly, basking is especially important in the dry season and leads to reduced energy consumption. It is like the sun is switching striped mouse activity on in the morning: as soon as the sun illuminates a shrub in which a group of striped mice is nesting, the striped mice become active and leave their nest to start sun basking. Striped mice with a nest which are illuminated 3 min later than another nests because of the shadow of a mountain will also become active 3 min later (Schradin et al. 2007). And as sunrise starts later during the course of the year (from summer to winter), the mice also start their activity a few minutes later from week to week. This is an example of how the abiotic environment can influence adaptive behavior.

Important aspects of the biotic environment that influence behavior are food and predators, both also being factors that influence population dynamics (predators: top-down; food: bottom-up regulation). Animals behave adaptively by foraging in a way that optimizes energy intake per time and simultaneously reducing the risk of death by predation. Thus, the distribution and abundance of both food and predators significantly influence animal behavior. Optimal foraging theory has been very successful in predicting how animals maximize energy intake per unit of time. How animals can remember their variable environment was experimentally tested using artificial flowers providing food to rufous hummingbirds (*Selasphorus rufus*), with the flowers being either refilled every 10 or every 20 min. This resembles natural

differences between plant species in nectar production. The hummingbirds were able to recognize the different artificial flowers, and they remembered where the flowers were and which flowers they had last drunk from (Henderson et al. 2006). Another example is provided by stickleback, small fish, which prefer areas with many daphnia, their own prey, as long as the areas are safe. But when one presents them the silhouette of a kingfisher, a stickleback predator, they prefer areas with few daphnia, probably because there they can increase their vigilance against their potential predator (Milinski and Heller 1978). In sum, animals evolved behavioral strategies to maximizing their individual fitness given the current ecological situation such as the limited food supply and the presence of predators and conspecifics (mates and competitors).

For most species, one of the most important aspects of their environment concerns their social environment. This consists of all conspecifics they encounter, which means potential mates, potential competitors such as same-sex neighbors, and their own offspring. Thus, a social environment does not only exist for group-living species but also for solitary species which have to find a mate and defend a territory. Defended territories contain important resources for survival and reproduction, which is why territories are aggressively defended against conspecifics. Territorial neighbors often recognize each other and show reduced aggression toward each other than to unfamiliar conspecifics. Thus, neighbors respect each other as “dear enemies” and as such each other’s territories, while floating and dispersing individuals which have no territories are heavily attacked (Temeles 1994). However, sometimes the territorial neighbor is a stronger competitor than the non-territorial floater. For example, in African striped mice, territorial males defend a group of two to four females with which they breed. In striped mice, extra-group paternity is high, and females especially mate with the familiar neighbors and not with the floating males. This can explain why in striped mice territorial males are much more aggressive toward their “nasty neighbor” than toward unfamiliar males, as this aggressive strategy could significantly reduce the amount of

extra-group paternity and thus increase their fitness (Schradin et al. 2010).

Living in groups creates its own, special social environment. This leads to significant costs, such as increased competition for food and mates and increased risk of the spread of disease. Group-living has evolved in species in which these costs of group-living are on average lower than the benefits group-living provides (Krause and Ruxton 2002). Benefits of group-living mainly fall into two categories: foraging and avoidance of predation (Krause and Ruxton 2002). Living in groups can make it easier to find good food sites, to catch prey, and to avoid competition for renewable food sources. Possible advantages of group-living referring to predator avoidance are (1) increased vigilance: A group will discover a predator sooner than a single animal. The sooner the prey is alerted, the faster the predator's chance of success will decline. (2) Dilution effect: When a predator attacks a group of ten animals and captures one, the probability of one individual being captured is ten times lower (10%) than if the individual would have been alone. (3) Encounter effect: Decreased probability of predator encounter per individual as detection of larger groups does not increase proportionally with group size. In other words, a predator is less likely to detect a group of ten than to detect ten single individual. (4) Group defense: A group may be able to defend itself against predators while a single individual may not. (5) Confusion effect: Predators take more time to capture a single prey individual if it is surrounded by other moving conspecifics than if it is on its own. Thus, the environment determines whether the costs or the benefits of group-living are higher. Group-living is expected to have evolved especially in environments in which food availability is high or can be increased by foraging in groups (low competition for food) and where predation pressure is high.

Apart from the function of behavior, which means how it increases fitness, the second ultimate question is about the phylogeny or evolutionary history of behavior. From an ecological point of view, here the question about the environment of the ancestor is important, because the trait evolved in this environment: what was the

function in previous generations, how did it increase fitness? In other words, the current environment in which we are measuring fitness consequences of behavior depending on abiotic, biotic, and social factors represents the previous environment for the next generations, an aspect of a species phylogeny. It is especially important to consider the ancestor's environment when it differs from the current environment. For example, this could explain why an observed behavior doesn't seem to lead to fitness benefits, because of an evolutionary mismatch due to environmental change. This is especially important in our current period of accelerated global change: will behavior (and physiology) that is now adaptive still be adaptive in future generations that might have to survive and reproduce in a different world with a different climate (Rymer et al. 2016)?

## Ecology and Evolved Mechanisms

The ultimately oriented field of behavioral ecology (including sociobiology) sometimes created the impression that ecology is only important to understand the ultimate, but not the proximate reasons of behavior. This is wrong for two reasons: (1) proximate mechanisms of behavior are evolved mechanisms that increase fitness; and (2) the proximate mechanisms work in the environment in which the individual shows its behavior; thus, the ecology is an important component of the proximate mechanisms. In sum, why specific mechanisms exist can only be understood when considering the ecology of a species.

Tinbergen (1963) regarded the responding central nervous system (CNS) as the behavioral machinery. He defined ontogeny of behavior as the "change of behavioral machinery during development." Thus, the question addressing causation is the question about the behavioral machinery leading to the observed behavioral pattern, and the question about ontogeny asks how this machinery develops until the observed behavior is shown. One point of confusion has been that ontogeny itself has a causal impact on the observed behavior: otherwise it would not make sense to study it! Although both ontogeny and the

**Ecology, Fig. 2** The difference between ontogenetic factors and the behavioral machinery. Ontogenetic factors occur over time before a behavioral response is shown, whereas the behavioral machinery (central nervous system, CNS) is directly connected in time with the behavior. Ontogenetic factors can occur at different times before

the behavior occurs, while the factors of the behavioral machinery occur together with the observed behavior. Arrow 1 represents a possible ontogenetic factor pre-partum, arrow 2 a factor occurring during infancy, arrow 3 a factor during the juvenile phase, and arrow 4 a factor during adulthood.

behavioral machinery cause behavior, there is a clear difference concerning the time when this occurs (Fig. 2). While ontogenetic factors occur before the behavioral response is shown, the behavioral machinery is directly connected with the behavior in time. When we observe a special behavioral pattern, the question concerning causation is “What is happening to induce the animal to show this behavior at this particular moment?,” whereas the ontogenetic question is “What previous circumstances have caused the animal to respond at this moment in this way?” For both questions, the environment in which ontogeny and causation take place plays an important role (Fig. 1).

During ontogeny, the individual develops its behavioral machinery that will later produce the observed behavior. The behavioral machinery mainly consists of the brain (central nervous system), but also the endocrine system, which influences the brain via its hormones. Importantly, the endocrine system itself is regulated by and as such part of the brain. In fact, the brain is the largest endocrine gland of the vertebrate body, secreting both traditional hormones and especially from the hypothalamus and the pituitary releasing hormones which influences the secretion of other endocrine glands. The development of the brain

and the endocrine system starts with the fertilized egg. Especially important periods occur during embryogenesis and infancy, when sensitive periods can occur. During these sensitive periods, hormones can have permanent organizational effects on the brain which influences adult behavior. Thus, the environment during early development is especially important for the development of the behavioral machinery. But ontogeny continues during adulthood and senescence, and the brain and endocrine system also change during adulthood. For example, learning represents a change of the brain that occurs throughout life. Thus, the process of ontogeny is continuous from fertilization of the egg until senescence and death, though sensitive periods occur that are especially important (West-Eberhard 2003).

How an individual develops depends on both its genotype and the environment in which it lives, representing the gene-environment interaction. For example, in many reptiles, the abiotic factor of temperature influences whether the embryo in the egg develops into a male or a female (Yatsu et al. 2015). Of course this also has very strong effects on the behavior of the adult, as many behaviors are sex specific. Biotic aspects influencing early development include hormones

circulating in the blood of pregnant mammalian females or in the eggs of birds, which influence the later behavior of the offspring. In Mongolian gerbils, males that developed between two male fetuses in utero were reported to show less paternal care than males that developed between two female fetuses, because they experience higher testosterone levels in utero (testosterone diffusing from the neighboring male fetuses), leading to the development of a more masculine and a less parental brain (Clark et al. 1997). The environment experienced as an infant or juvenile can also influence paternal response as an adult. Growing up in a family group and experiencing paternal care leads to higher levels of paternal care in adult rodents (McGuire 1988). In rodents, maternal effects significantly influence stress response and social behavior of the offspring, which is an adaptive response to specific environments. For example, when female rats show increased levels of licking and grooming toward their pups, this decreases the stress response of her offspring when they are adult and as such also influences their behavior (Weaver et al. 2004). In sum, abiotic, biotic, and social factors influence the development of individuals, including the development of their behavioral machinery and, thus, their behavior.

The environment plays an important role in causing the brain (behavioral machinery) to show a specific behavior. It is stimuli from the environment that trigger a behavioral response. One simple abiotic stimulus that has great consequences on behavior is weather. For example, activity of African striped mice is delayed or even inhibited on cold rainy days when they remain in their nests instead of leaving for foraging (Schrader et al. 2007). The study of stimuli triggering behavior was one main focus at the start of the studies of animal behavior (Tinbergen 1966) but receives very little attention in current research. For example, early studies in the field of animal behavior tried to identify the so-called Schlüsselreize (sign stimuli) that triggered very fixed behavioral responses, the so-called fixed action patterns. Fixed action patterns are behaviors believed to be hard wired into the nervous system, representing instinctive and inherited behavior. Tinbergen studied the red belly of male

sticklebacks as a sign stimulus triggering aggression in territorial male sticklebacks. For this he created a series of simplified dummies representing sticklebacks, identifying that it is not the form of the dummy but only the presence of a red belly that triggers aggression (Tinbergen 1966).

Environmental stimuli are important for animals to show their behavior at the appropriate time and appropriate place. For example, parental care has to rely on appropriate stimuli indicating where and when individuals (and thus the parental brain) should respond with caregiving behavior, allowing them to recognize their young and their needs. Males might recognize young as their own if they are associated with their mate. Male laboratory mice (*Mus musculus*) are more likely to kill their own pups in the nest of a strange female than to kill strange pups in the nest of a familiar female. Male deer mice respond paternally to strange pups that are together with their mate but kill their own pups when these are associated with a strange female (Brown 1993). Males might recognize young as their own offspring when they are associated with a special place. Male mice show paternal care toward pups in their own home cage but show infanticide toward pups in the home cage of a strange male (Elwood and Kennedy 1991). Many bird parents take care of any chick in their own nest, as has been shown experimentally by placing additional strange chicks in a nest. However, they often ignore their own young if they are placed just a few centimeters away from the nest. The monogamous and biparental desert wood louse (*Hemilepistus reaumuri*, Isopoda) recognizes its own young from family-specific odors and kills and eats strange young (Linsenmair 1972), while king penguin chicks recognize their parents coming back from sea by their individual calls (Jouventin et al. 1999). Thus, multiple and different stimuli from the environment such as the place, the smell, or the sound trigger adaptive behaviors to be shown.

## Ecophysiology of Cognition

How smart does an animal have to be? A penguin knows everything it has to know and can do everything it needs to do. It won't be more

successful if it would have the intelligence of a monkey or of a human being! Thus, the cognitive abilities of a species depend on the environment in which it lives. Cognition is a product of evolution. Cognitive traits are selected to closely match the cognitive demands posed by each species' environment. Thus, specialized cognitive abilities evolved as a response to specific environmental demands while general cognitive abilities are present in most or all species. As such, cognitive performance can differ between species due to evolutionary adaptation. But cognitive performance can also differ between populations due to phenotypic plasticity and within populations and individuals due to phenotypic plasticity. A specific cognitive trait only evolves if the benefits are higher than its costs. To understand cognition, one has to find answers to the four questions of Tinbergen, and each depends on the environment. The proximate causes, including the physiological state of an individual, influence cognition, have ultimate fitness consequences.

While one field of cognitive research has focused on variation in cognitive abilities of animals in its ecological context and how this increases fitness (Healy and Braithwaite 2000), another has focused on the influence of physiology on cognition (the proximate mechanisms) under highly standardized laboratory conditions (e.g., Neese and Schantz 2012). Few field studies have addressed the relationship between metabolism, hormones, and cognitive traits under natural conditions. Seasonal changes in hormone secretion might have pronounced effects on cognitive performance, as do seasonal changes in blood glucose levels. For example, low blood glucose level during periods of low food availability might negatively influence both behavior and cognition, because insufficient energy is available to optimally run these processes (Fig. 3). Low food availability in the environment leading to starvation can also affect cognition. Whether starvation has a positive or a negative effect on cognition might depend on the phase of starvation. As starvation first activates glycogen stores, it can first improve cognition, but as starvation continues, reduced energy availability will negatively affect cognition (Maille and Schradin 2017). This is especially the case in free-ranging animals. In

contrast, obese humans and obese domestic and zoo animals might have improved cognitive abilities when been food deprived, as this can increase their health status.

Cognition is a function of the central nervous system, which consumes a significant amount of energy. For example, in humans, 20% of the resting metabolic rate is due to the metabolic costs of the human brain although it represents only 2% of the body mass (Laughlin 2001). The generation and propagation of neural signals increase energy consumption, and the storage of information requires additional neural tissue, either in the number of neurons or in the number of connections between these neurons, which further increases the energetic demands of the brain. The supply of metabolic energy is supposed to constrain the growth and function of the brain and consequently the cognitive performance. The capacity of the brain to store energy is very limited. As such, an ecological decrease in food availability, for example, due to seasonal changes, is likely to affect brain functions and cognition and behavior as well (Fig. 3).

In sum, cognitive performance is based on brain functions, which have energetic demands and are modulated by physiological parameters such as metabolic hormones. As both environmental demands and environmental energy availability change seasonally, cognitive performance in free-living animals can also change seasonally. Environmentally induced changes in physiological traits, such as blood glucose and hormone levels, influence cognitive performance in free-living animals. Individuals spending more energy than they can currently obtain from their environment face a trade-off of investing energy into cognition, into other life sustaining processes, or into reproduction. Selection pressures such as predation risk, mate choice, or social demands act on the trade-off between energy-saving and cognition. Different environmental conditions can lead to three different trade-off outcomes: cognitive impairment, resilience, or enhancement (Maille and Schradin 2017). If cognition is very important, then the organisms will still allocate the same amount of energy to cognition, while reducing energy spent for other processes, such as reproduction. Further, not only food

**Ecology, Fig. 3** Energy flow in the African striped mouse (*Rhabdomys pumilio*) from a semidesert habitat in South Africa, during (a) the moist breeding season in spring with high food availability and (b) the dry non-breeding season in summer with low food availability. The African striped mouse can only reproduce in the moist season when sufficient food and thus energy is available. Black arrows indicate effects on fitness. White

arrows represent energy invested in one process: thickness represents amount of energy. Energy availability in the environment influences both behavior and cognition. This figure illustrates how the environment influences both proximate factors and ultimate consequences of cognition and behavior via its changes in food availability (Figure adapted from Maille and Schradin (2017))

availability but also other aspects such as predation pressure can change seasonally. Cognitive impairment occurs when periods of food shortage are also periods of low cognitive demands. Cognitive resilience occurs when cognition helps to stabilize or improve the physiological state in challenging environments (Buchanan et al. 2013). Cognitive enhancement occurs when cognition allows a net benefit in the energy budget. Thus, the environment has a significant influence on cognitive performance, and this influences an individual's fitness. The emerging field of eco-physiology of cognition studies how physiological changes affect cognition in free-living animals exposed to natural environmental variation, such as seasonal variation in food availability and temperature (Maille and Schradin 2017).

## Conclusion

Behavior and cognition cannot be understood without taking the ecology into account. The

environment in which an individual lives influences the development, causation, and fitness consequences of its behavior and cognition, and as such also the phylogeny of behavioral and cognitive traits of future generations. Animals have evolved physiological mechanisms that allow them to maximize their evolutionary fitness giving the environment in which they live. Thus, they have evolved to deal with ecological problems, especially food availability and predation pressure. While nothing in biology makes sense except in the light of evolution, evolution and behavior cannot be understood without taking the ecology of a species into account.

## Edward B. Titchener

Nancy Digdon  
Grant MacEwan University, Edmonton, AB,  
Canada

## Introduction

Titchener, Edward Bradford (1867–1927) is best known for his system of psychology called structuralism. It was an experimental psychology that studied the structure of human consciousness by identifying its smallest elements.

## Early Years and Education

Titchener was born in Chichester, England, on January 11, 1867 to John and Alice (nee Habin) Titchener. His ancestors had lived in Chichester since the 1500s and many had been wealthy and influential (see Boring 1927 for more detail). But

Titchener's paternal grandfather lost the family fortune and died poor. Financial hardship persisted and was exacerbated when Titchener's father died while still in his 30s.

Without financial assistance from family, Titchener attended elite schools on academic scholarships. He graduated from the prestigious Malvern College before entering Oxford University at the age of 18 to complete an A.B. degree (1885–1890). He studied philosophy, classics, Greek, and Latin and conducted supervised research in physiology. Titchener was also active in extracurricular hobbies. He was an accomplished musician, a skilled tennis player, an avid naturalist, and a voracious reader of diverse writings in several languages. His reading of Wilhelm Wundt's German publications about a new science of psychology that investigated human consciousness in the laboratory peaked Titchener's interest and shaped the direction of his career.

In 1890, Titchener moved to Leipzig, Germany, for 2 years where he completed a PhD under Wundt's supervision. After finishing his PhD, Titchener's goal was to move back to his homeland so that he could establish experimental psychology at a British university; however, none were hiring experimental psychologists. While in Wundt's lab, Titchener met American students and one of them (Frank Angell) suggested Titchener apply for an experimental job at Cornell University in Ithaca, N. Y. In 1892, 25-year-old Titchener crossed the Atlantic to become the Director of the psychology laboratory at Cornell University, and he remained at Cornell until retirement.

## Structuralism System of Psychology and Laboratory Science

Titchener's structuralism system of psychology was a pure experimental science conducted in the laboratory with specialized equipment (like that used in Wundt's lab). Titchener had a six-room laboratory and he immediately purchased or made the necessary equipment for his scientific investigations.

In his research, Titchener used a method of introspection that required scientists to direct their observation inward on their own consciousness in order to record the smallest elements of sensations, images, or feelings that they experienced under various controlled conditions. Titchener argued that his method of introspection was scientific because it was a form of systematic observation. But he cautioned that “when we introspect, we must be absolutely impartial and unprejudiced. . . We ought to be ready to take the facts precisely as they are. . . Impartiality is a necessary condition of all scientific observation” (Titchener 1896, p. 45). Titchener’s introspection required expert training in order to detect the elements in consciousness. Introspection experts avoided the “stimulus error,” which was to say the name of the stimulus, such as saying “rose” when shown one, rather than correctly saying the sensory elements involved in the conscious experience of it (e.g., “red,” “softness,” and “silkeness”). Titchener believed that the work of well-trained introspectionists would reveal the structure of the generalized human mind.

Titchener likened his analysis of the elements in consciousness to the analysis that physical scientists had done when constructing the periodic table of the elements of the physical world. By 1896, Titchener had already discerned more than 44, 435 elementary sensation qualities, including 32,820 related to the eye; 11,600 to the ear (audition); 4 to each of the tongue and skin; 2 to the muscle; 1 to each of the ear (static sense), sex organs, tendon, and joint; and possibly other sources of elements that he was uncertain about, including the alimentary canal, blood-vessels, lungs, and tongue (Titchener 1896). Titchener wrote extensively about his structuralism between 1893 and 1900, publishing 62 research articles and 2 books about it. Most research articles are in *The American Journal of Psychology*, which Boring (1927) dubbed the “mouthpiece” for psychology at Cornell. Titchener served as Associate Editor (1895–1920) and Editor (1921–1925) of this journal, and had some control over what was published therein. Titchener quickly rose through the academic ranks, being promoted to full Professor in 1898 when he was only 28-years-old.

In Titchener’s 1898 article, titled *The Postulates of Structural Psychology*, he contrasted structuralism with alternative psychologies in the USA at that time. According to Titchener, the other psychologies were problematic because they investigated the function of consciousness (without being sufficiently informed about its structure), focused on individual differences (instead of using science to understand the generalized human mind), or attempted to apply psychology (e.g., mental testing), which Titchener believed detracted from psychology’s status as the pure experimental science of the structure of human consciousness.

Titchener was a powerful figure at Cornell, and his structuralism defined the psychology department for the 35 years that he was there. But Titchener’s structuralism was not popular among American psychologists who had no ties to Cornell. The use of a psychology laboratory and specialized equipment, however, did become the norm for teaching psychology at other American universities. Thus, when Titchener (1901) published his student and instructor manual for laboratory practice, it was widely adopted by other universities even though the adoptees did not accept structuralism. As one reviewer of Titchener’s manual exclaimed,

Professor Titchener has here placed at the disposal of his colleagues the result of years of very special and successful devotion to the problems of psychology susceptible to treatment by the experimental methods, and for this service so admirably accomplished he is entitled to the honors and privileges attaining to the distinction of carrying through so difficult and important piece of pioneer work. (Jastrow 1901, p. 743).

Titchener further promoted laboratory research by publishing another textbook (see Titchener 1910) and by organizing his Experimentalist Group. This group met annually in psychology laboratories across the country to have frank discussions about new research or research still in progress. Attendance at these events was by Titchener’s invitation only. He barred women so that the male attendees had the liberty to behave in ways considered unsuitable for female audiences. Titchener, however, did not exclude women from Cornell’s PhD program or from his own

laboratory, in contrast to other prominent universities that were male only at that time (e.g., Clark University and Harvard University). Titchener's first PhD student was Margaret Floy Washburn. When she earned her PhD in 1894, she was the first woman to have a PhD in psychology from an American university.

## Titchener's Ties to Comparative Psychology

Titchener was clearly interested in comparative psychology even though he did not include it as part of his structuralism system of psychology. Indeed, Margaret Floy Washburn's PhD was based on animal research. And Titchener helped Washburn publish her 1908 book, *Animal Mind*, with the company that published his own books (i.e., Macmillan Company).

Although rarely cited today, Titchener has 10 short publications about comparative psychology/biology topics that are in the journal *Nature* between 1889 and 1894. See Dewsbury (1997) for a list of these references. In these publications, Titchener reported his observations that the color of bird eggs seemed unrelated to the color of the nest and its surroundings; his experiments on the palatability of different insects fed to mice and other small animals; his observations of which birds had a serrated edge on the third digit of their claws (called pectination) and how the birds used it; and his observations of mate preferences in birds and insects.

In addition to these publications in *Nature*, Titchener authored and co-authored English translations of Wundt's works, which included the 1894 lectures on *Human and Animal Psychology* and their revisions in 1896 and 1901 (see Boring 1927 for these references).

## Adjustment to Life in America

Two years after moving to America, Titchener married Sophie K. Bedlow from Portland Maine. As their children grew, the Titchener family hosted Sunday evening orchestral performances by family and musical people affiliated with

Titchener's laboratory, as told by Titchener's former PhD. student, Edwin Boring. Titchener lived in America for 35 years, up until his sudden death from a brain tumor in 1927 at age 60. However, Titchener never became "Americanized" or an American citizen. As Heidbreder (1933) tells it,

...only two years at Leipzig had Germanized him. He even looked like a German and was sometimes mistaken for one; the science for which he labored was German to the core; and it what must have seemed to him a crude university on the wrong side of the Atlantic, he preserved with sturdy and punctilious devotion the ceremonial with which he had seen psychology surrounded in a German university. (p. 114).

Boring (1927) noted that Titchener became isolated from his laboratory in his later years. Boring recalled that "In June Titchener came to the Laboratory for doctors' examinations, but I do not think that in seven years (perhaps seventeen) he was once in the Laboratory between June and February. Graduates saw him at the house and not often" (p. 501).

From 1917 to 1927, Titchener published on a wide range of topics that went beyond his structuralism system of psychology. See Dallenbach (1928) for a bibliography of Titchener's writings during that period. Titchener also developed expertise in deciphering the meaning and significance of the inscriptions on ancient Greek, Roman, Chinese, and Mohammedan coins, and collaborated with Howland Wood, the curator of the American Numismatic Society.

Late in life, Titchener worked on a book titled *Systematic Psychology*, in which he questioned the utility of structuralism and the breaking down of consciousness into elements. Instead, he argued for what he called a phenomenological or existential approach, which examined consciousness as it occurred without breaking it down. Titchener died before finishing this book, but his writing-in-progress was published after his death (see Titchener 1929).

In closing, Titchener's significance to psychology was summed up in his obituary:

The death of no other psychologist could so alter the psychological picture in America. Not only was he unique among American psychologists as a personality and in his scientific attitude, but he was a cardinal point in the national systematic orientation. The clear-cut opposition between behaviorism and

its allies, on the one hand, and something else on the other hand, remains clear only when the opposition is between behaviorism and Titchener, mental tests and Titchener, or applied psychology and Titchener. His death thus, in a sense, creates a classificatory chaos in American systematic psychology. (Boring 1927, p. 377).

Titchener's system of structuralism dwindled at Cornell after his death. However, a piece of him remained; his brain is in the Wilder Brain Collection managed and displayed by the Department of Psychology.

## Edward C. Tolman

Nancy Digdon  
Grant MacEwan University, Edmonton, AB,  
Canada

Edward Chase Tolman (1896–1959) developed purposive behaviorism. He studied rats in mazes and the routes they chose to get to the end of the

maze. The rats behaved as though they had a mental map of the maze. The rats' performance in the maze also varied depending on whether they got desirable foods at the end of the maze.

## Early Years and Education

Edward Chace Tolman was born and raised in West Newton, MA. His family was committed to humanitarian causes, social justice, and pacifism, which reflected the values of their Quaker and Unitarian Church ancestors (see Carroll 2017 for a detailed biography of Tolman and his ancestors). After high school, Tolman earned a BSc in electrochemistry from Boston Tech [which is now called the Massachusetts Institute of Technology (MIT)]. He chose this program because he was good at high school math and science and because his father wanted him to get appropriate training so he could contribute to the family business, J. P. Tolman & Co., which was known for manufacturing quality hemp cord. But after finishing his BSc in 1911, Tolman was uncertain about his career path. He read William James's (1890) *Principles of Psychology*, which sparked an interest in academic philosophy as a possible career, and this prompted him to take two summer courses at Harvard, one in philosophy and the other in psychology. These summer courses helped Tolman crystalize his career plans. In his autobiography, he writes, "I decided then and there that I did not have brains enough to become a philosopher. . . but that psychology was nearer my capacities and interests. It offered, at that date, what seemed a nice compromise between philosophy and science" (Tolman, 1952, p.323).

Tolman completed a PhD in psychology at Harvard in 1915, with the support of his father, who respected his son's intention of using psychology for the betterment of human lives. Tolman's dissertation was on human memory and was supervised by Hugo Münsterberg. The dissertation had an appendix with supplementary research on the effects of a change of purpose on memory, which foreshadowed Tolman's later development of purposive behaviorism (which is described in the next section). Importantly, the dissertation research used the method of

introspection, which relied on people's verbal accounts of their mental experiences. The results were unreliable and uninterpretable. Tolman's dissertation research caused him to doubt the utility of introspection as a scientific method. Moreover, in his final year, he took a comparative psychology course taught by Robert Yerkes. Tolman was introduced to behaviorism and animal research via the course's textbook, which was John B. Watson's (1914) book, *Behavior: An Introduction to Comparative Psychology*. While a graduate student, Tolman also became familiar with Gestalt psychology and Kurt Lewin's field psychology, whose influences are evident in Tolman's later work.

Tolman's first academic job was teaching at Northwestern University in Evanston, Illinois from 1915 until his dismissal in 1918. In his autobiography, Tolman writes that he was let go because he had.

a compulsion for research and writing, although it did not result in a large output at the time, (it) interfered with my learning to become much of a teacher. . . Further, this was just before we got into the first World War and my pacifist training, plus my own problems about aggression, kept me in a terrific emotional turmoil so that I did a still poorer job. (Tolman 1952, p. 327).

In 1918, Tolman was already married (to Kathleen Drew) and had an infant daughter (Deborah). He and his family moved back to his parents' home in Newton, and Tolman worked briefly as a laborer in a garden market until he received a job offer from Berkeley in California.

## Research Career at Berkeley and the Development of Purposive Behaviorism

In 1918, Tolman and family moved to Berkeley where Tolman was to produce his major works in the ensuing decades. In 1919, Tolman acquired his first white rats and shifted his research from human studies to laboratory studies of how rats behave when placed in different mazes under controlled conditions and experimental manipulations. As a result of this research, Tolman became skeptical of Watson's version of behaviorism that focused on the specific muscle

movements in a conditioned reflex as being the central units of behavior. Tolman published a theoretical paper in 1922, in which he argued that what a behavior accomplished, or the function it served, were more important than the specific muscle movements used in carrying out the behavior. Tolman called his version of behaviorism "purposive behaviorism." Moreover, he argued that behavioral methods could be devised to study "mental concepts" such as thinking, consciousness, learning, ideas, and emotions in an objective way that did not involve references to mental states or the use of introspection. Tolman's 1932 book, *Purposive Behavior in Animals and Men*, further articulated this argument and introduced the concept of "molar behaviorism" to denote that a behavior's purpose (or function in terms of meeting a goal) were important emergent properties that were missed when the study of behavior was restricted to a fine grained molecular analysis of each of the small, specific muscle movements involved in doing the behavior.

Tolman's lab produced several clever studies in support of his version of behaviorism. One example is the empirical demonstration of "latent learning," meaning that learning could occur without an immediate change in performance. In this research, rats were randomly assigned to one of three groups. All rats were partially food deprived when they navigated the same maze on multiple trials, but each group did so under different conditions. Group 1 rats always encountered food at the end of the maze. They gradually made fewer and fewer wrong turns and "errors" in getting from the start of the maze to the food at the end. Group 2 rats received no food at the end of the maze, and their rate of wrong turns and errors did not improve across trials. Group 3 rats received no food on the first ten trials, and their performance was similar to that of the group 2 rats. But after the 10th trial, group 3 rats encountered food at the end of the maze on every trial. The key finding is that group 3 rats had a sharp drop in wrong turns and errors once trials were associated with food at the end of the maze. Their performance improved at a faster rate across trials compared to the rate of improvement seen in the group 1 rats who had encountered food since the start of the study. Other examples of innovative research pertain to

the concepts of “insight,” “sign-gestalts” and “cognitive maps.” Tolman (1932) gives a detailed account of these other topics.

Tolman achieved national prominence when he was elected president of the American Psychological Association in 1937. In his presidential address (see published version in Tolman 1938), he contrasted his behaviorism with that of a contemporary rival, Clark Hull. Tolman took issue with Hull’s strategy of reducing behavior to stimulus-response connections and the mathematical learning laws that govern them. Tolman argued that a rat’s behavior at a “choice point” in a maze was determined in part by a host of intervening variables that operate between the stimulus and the response, which Tolman believed Hull’s theory neglected. Examples of these intervening variables are the rat’s hereditary makeup, past training/experiences, and the rat’s current motivational state in terms of appetites or aversions. Tolman conducted most of his research using rats as subjects, but he believed that many phenomena found in rats were general enough to apply to other species including humans.

## Social Issues and Social Activism

In addition to developing purposive behaviorism and conducting experiments, Tolman was an active member of the Society for the Psychological Study of Social Issues (SPSSI), which was established in 1936. This society gave psychologists an opportunity for united efforts against major social issues of the day, including world hunger, racism, labor union/management friction, the rise of fascism, and the threat of a second world war. Tolman was Chairman of SPSSI when the USA entered World War II, and he published a paper about SPSSI’s relevance (see Tolman 1941) and a book on psychological insights into the causes and the prevention of war (see Tolman 1942).

After World War II, the USA was embroiled in the cold war over nuclear arms and concerns that communism could infiltrate and supplant American culture. Berkeley, like other American universities, required its professors to sign a loyalty oath

proclaiming they had no ties to communism. Faculty refusing to sign were fired (see detailed account in Carroll 2017). Although Tolman had no ties to communism, he refused to sign the loyalty oath on the principle of faculty rights. Tolman emerged as a leader in the non-signers’ fight against the university. Ultimately the California Supreme court ruled in favor of the non-signing faculty and they were reinstated.

Toward the end of his life, Tolman reflected upon his life’s work and his system of purposive behaviorism:

The system may not well stand up to any final canons of scientific psychology. But I do not much care. I have liked to think about psychology in ways that have proved congenial to me. Since all the sciences, especially psychology, are still immersed in such tremendous realms of the uncertain and the unknown, the best that any individual scientist, especially any psychologist, can do seems to be to follow his gleam and his own bent, however inadequate they may be. In fact, I suppose that actually this is what we all do. In the end, the only sure criterion is to have fun. And I have had fun. (Tolman 1959, p. 152.)

## Introduction

Edward Lee Thorndike was born 31 August 1874 in Massachusetts. Thorndike was introduced to psychology during his junior year (1893–1894) at Wesleyan University, during which he read chapters of William James' *The principles of psychology*. Thorndike subsequently attended Harvard University, with the intention of taking courses on English literature and the French language and earning a master's degree in teaching. During his first year (1895–1896), he attended courses taught by Josiah Royce and William James, and thereafter psychology increasingly became his focus. By the

time he earned his master's degree (1897), Thorndike had begun to research animal learning and had decided to earn a Ph.D. and teach psychology. Thorndike completed his doctoral dissertation in 1 year at Columbia University, under the direction of James McKeen Cattell. His dissertation (*Animal Intelligence: An Experimental Study of the Associative Processes in Animals*) was an instant classic and described the puzzle box experiments for which he is best known. After graduation, he taught for 1 year at the College for Women at Case Western University. He spent the remainder of his career at the Teachers College at Columbia University. Thorndike is most famous for his contributions to learning theory, but his interests were wide-ranging. He wrote several seminal books on educational psychology and classroom instruction. He assisted the United States Army during World War I in developing aptitude tests for recruits and selecting aviators for flying schools. After the war much of his research was concerned with human learning, intelligence, and intelligence testing. During the 1930s and 1940s, he additionally completed a number of studies concerned with social psychology and personality. Thorndike served as the president of the American Psychological Association (1912) and the Psychometric Society (1937). He retired from Columbia in 1940, but continued scholarly writing. Thorndike died 9 August 1949 in New York. By the time of his death he had amassed more than 500 publications. He is one of the most influential psychologists of the twentieth century (Hagbloom et al. 2002) and arguably the greatest of all the learning theorists (Olson and Hergenhahn 2009).

## Initial Animal Research

At Harvard Thorndike began performing research with chickens under the direction of William James. He is thought to have been the only student performing animal research at Harvard at the time; he chose this research, he wrote, “not because I knew animals or cared much for them, but because I thought I could do better than had been done” (Joncich 1968, p. 89). Chickens offered several advantages over other species: they were

relatively easy to acquire, they required little room or expense, and they quickly matured. Thorndike studied chicks' instinctive reactions at different ages to a range of aversive or potentially aversive stimuli (such as water, the presence of a live kitten or a stuffed owl, candle flames, or a football thrown into the chicks' pen).

## Puzzle Box Experiments

Thorndike's most famous research is the dissertation he completed at Columbia (1897–1898), especially the section describing how cats learn to escape from puzzle boxes.

The subjects in this research were 12 cats (strays that he had caught), and all but one was under a year in age. He tested the cats in 15 boxes he constructed. In each box it was possible for the cat to escape through a door, otherwise the boxes were differently configured. For example, in one box the door could be opened by depressing an external bar that held the door in place. The cat could reach this bar by placing a paw through the wooden slats near the door. In another box the door could be opened by pulling on a string inside the box that was connected to a bolt holding the door closed. The simplest box required a single act to open the door; the most complex required three actions. After the cat opened the door, it was able to eat food that had been placed outside the box.

On each trial, Thorndike placed the subject in a particular box and recorded the time until escape occurred. He observed that the cat's behavior was initially variable. The subject would appear to wander around the box and meow, seemingly looking for a way to escape. Thorndike (1898) wrote:

It tries to squeeze through any opening; it claws and bites at the bars or wire; it thrusts its paws out through any opening and claws at everything it reaches; it continues its efforts when it strikes anything loose and shaky; it may claw at things within the box. It does not pay very much attention to the food outside, but seems simply to strive instinctively to escape from confinement. The vigor with which it struggles is extraordinary. For eight or ten minutes it will claw and bite and squeeze incessantly. (p. 13).

At some point the subject would make, seemingly by accident, the response that opened the door. He observed that on subsequent trials the time until escape occurred tended to decrease. In Thorndike's (1898) words:

Starting, then, with its store of instinctive impulses, the cat hits upon the successful movement, and gradually associates it with the sense-impression of the interior of the box until the connection is perfect, so that it performs the act as soon as confronted with the sense-impression. (p. 15)

In other words, the cat learned to connect the situation (a stimulus) to a particular response. He reasoned that the stronger this connection became, the more quickly escape would occur. When he examined how latency to escape varied across trials, he observed that the data appeared to follow an irregular curve. Thorndike (1898) argued that this "time-curve" provides "a fair representation of the progress of the formation of the association. . ." (p. 16).

Subjects were studied in the simplest boxes first. All cats learned to escape from boxes that required only a single response. Thorndike found that cats were less consistently able to learn to escape when multiple responses were required.

Thorndike found little evidence that the cat's learning was affected by insight. He reasoned that if the cat could act based on an idea of how the door was opened, then once it obtained this idea there would be an abrupt shift from long escape latencies to short escape latencies. Instead, Thorndike observed only gradual and irregular time-curves. He additionally observed that a cat's "instinctive impulses" (e.g., meowing, clawing at different parts of the box) were slow to disappear when they did not aid in escape; this also seemed inconsistent with the cats having an idea of how the puzzle boxes worked.

Thorndike considered animals' cognitive abilities. For example, he tried to show the cat how to make the response by holding its paw and putting it through the proper motions, but this did not change the subject's behavior. He gave novice cats the opportunity to observe experienced cats make the appropriate response, but this also did not facilitate learning. He also observed how cats adjusted to being placed in a new box. He

observed that the cats would attempt to make a response that had worked before, even if the response was not available in the new box. For example, if a cat had learned to escape by pulling on a loop inside the box, it would continue pawing at that spot even if the loop was not there. Based on these observations, Thorndike concluded that a cat's learning was mostly or solely based on the incremental development of a stimulus-response (S-R) connection.

Thorndike also placed three dogs in puzzle boxes (which of course were larger than those used with cats). In so doing, the puzzle box experiments contributed to the nascent field of comparative psychology. Thorndike quickly found that dogs differed from cats both in their "instinctive impulses" and in learning. He observed, for example:

A dog... is not nearly so vigorous in his struggles to get out as is the young cat... He paws or bites the bars or screening, and tries to squeeze out in a tame sort of way. He gives up his attempts sooner than the cat, if they prove unsuccessful. Furthermore his attention is taken by the food, not the confinement. He wants to get *to* the food, not *out of* the box. (1898, p. 32).

Thorndike's dogs succeeded in learning to escape from the simplest boxes, but they were less successful than cats in learning to escape from more complex boxes. He attributed this difference to motivational factors rather than to a difference in how learning occurred in dogs. He noted, "It was... a practical necessity that the dogs should be kept from howling in the evening, and for this reason I could not use as a motive the utter hunger which the cats were made to suffer" (1898, p. 32).

## Other Animal Studies

Thorndike believed there may be an abundance of methods that can be used to study animal learning. Thorndike followed his puzzle box experiments with studies performed with chicks, fish, and Cebus monkeys. The chicks were placed in simple mazes built chiefly from books that were set on end. Escaping from the maze caused the chick to

return to its home pen (where there were food, water, and the other chicks). The fish learned to find an opening in a barrier that led to a part of an aquarium where there was food and shade. The monkeys learned to open a box set next to their cage in order to obtain a piece of food. In all three cases, Thorndike obtained "time-curves" that resembled those from cats and dogs in puzzle boxes.

Thorndike (1901) observed instances in which a monkey showed "a rapid, often apparently instantaneous, abandonment of the unsuccessful movements and a selection of the appropriate one which rivals in suddenness the selections made by human beings in similar performances" (p. 15). In other words, it appeared that monkeys *could* learn from an idea of the task. However, he was reluctant to accept this interpretation because gradual time curves characterized the more difficult tasks and he felt there was no reason why ideas would affect how subjects learned simple tasks and not complex ones. Thorndike concluded that the rapid learning was more likely due to other factors. He noted that "monkeys obviously form more associations and associations in a greater variety than do the other mammals" and that they have an "instinctive curiosity or tendency to fool with all sorts of objects" (1901, p. 18), which would facilitate learning to open a box.

## Connectionism

Thorndike ceased conducting animal research after taking positions at Case Western University and Columbia University. However, Thorndike continued to write about the apparent nature of animal learning and to describe this learning in terms of general principles and laws.

Thorndike stated that there are general laws controlling behavior. Firstly, he maintained that that behavior is predictable; "Every response or change in response of an animal is then the result of the interaction of its original knowable nature and the environment" (1911, p. 242). The original nature of an animal includes "instinct," that is, "inherited... connection-and action-systems" (Thorndike 1911, p. 243). How these connections

functioned depended on circumstances, along with motivation, fatigue, illness, aging, and other variations in the state of the organism.

Thorndike believed that when an organism encounters a novel situation, its behavior will be varied (he termed this the principle of varied reaction). If the subject's initial action does not produce satisfaction, then a change occurs within the organism that makes a different action more likely. When an action finally occurs that leads to satisfaction, a connection will form between the situation and the response. The strength of this connection determines how likely the situation will lead to a repetition of the action in the future.

Thorndike believed several factors affect an acquired S-R connection. One factor is whether the outcome is "satisfying" or "dissatisfying" to the subject. (He also used "reward" in place of satisfaction and "discomfort" or "annoyingness" in place of dissatisfaction). Thorndike believed that more satisfying outcomes produced stronger S-R bonds and that more dissatisfying outcomes produced weaker S-R bonds. He termed this principle the law of effect. Thorndike also believed that the connection became stronger every time a stimulus led to a particular response and that it became weaker every time a response failed to occur when a particular stimulus was present. He termed this principle the law of exercise.

A third factor that Thorndike emphasized was the "readiness" for a connection to occur. Readiness, he believed, is in part innate. For example, an organism is generally more ready to eat than vomit, or laugh than hiccup. Readiness is also affected by the state of the organism. For example, an organism becomes more ready to eat when it is hungry, or less ready to play when it is tired. In addition, readiness is affected by features of the situation that cause the organism to anticipate that a stimulus-response connection will be activated. For example, Thorndike (1913a) wrote, "When a child sees an attractive object at a distance, his neurons may be said to prophetically prepare for the whole series of fixating it with the eyes, running toward it, seeing it within reach, grasping, feeling it in his hand, and curiously manipulating it" (p. 126). Thorndike believed that readiness helps determine how the organism is affected by

activation of a stimulus-response connection. According to the law of readiness, satisfaction comes from activity among neurons that are ready for activity, and annoyingness comes from an absence of activity for which the organism is ready, or activity for which the organism is not ready. Thorndike (1932) also believed that "learning may consist in changing the readiness of connections as truly as in changing their strength" (p. 329).

While effect, exercise, and readiness largely determined the strength of a connection, he acknowledged that the particular manner in which the stimulus was presented and the response occurred were also factors in learning. Learning was facilitated, for example, if a response and its effect were temporally contiguous. Learning was also affected by the attention that the subject gives to its actions. For example, Thorndike suggested that if a cat accidentally made the response leading to escape with its nose while trying to claw at an opening, then the S-R association will develop more slowly than it would if the response had been made intentionally (Thorndike 1911, p. 249). In addition, he attributed importance to a somewhat nebulous concept termed "set," which involved an organism's attitude or determination to act in a particular circumstance. For example, he believed that a person who is interested in topic and motivated to learn will learn differently than someone who is neither of those things. In animal experiments, set may be affected by physical maturation, hunger, fatigue, and prior learning. For example, a cat that has succeeded in learning to escape from a series of puzzle boxes in the past is more likely to show greater determination to escape when placed in a novel box than are other, inexperienced cats. The differing "set" of the experienced cat might cause it to attend differently to the parts of the puzzle box, or to make more definitive movements when, say, depressing a bar or pulling on a string inside the box.

Finally, Thorndike described factors affecting the transfer of learning from one situation to another. He believed that a situation may consist of a number of different stimuli or elements and that certain elements may be more important in producing the response than others (he termed

this the principle of prepotency of elements). In a new situation, an S-R connection will be activated so long as the new situation resembles a situation in which a response occurred before (the law of assimilation); this is especially true if prepotent elements are present in the new situation. He also believed that the transfer of learning could be facilitated through a principle termed associative shifting. According to this principle, when there is a relationship between some set of stimuli and a particular response, it is possible to gradually replace certain elements of the stimulus set with others without eliminating the response. In this way, an entirely new set of stimuli can be made to produce the response. “Thus, what was at the start utterly without power to evoke a certain response may come to do so to perfection” (Thorndike 1913b, p. 15–16).

Thorndike generally attributed the formation of S-R connections in animals to “learning by trial and accidental success” (Thorndike 1901, p. 2). Although his research had yielded little evidence that animals can learn through observation or by reasoning and using ideas, he thought it obvious that these forms of learning occurred in humans. Indeed, he attributed to learning by ideas “practically all the advances in civilization” (1901, p. 2). In later years he became less certain and suggested that “higher forms of learning” might be found to be reducible to readiness, the action of connections, and other S-R concepts (Thorndike 1932).

In total, Thorndike’s theory came to be known as “connectionism” (e.g., Olson and Hergenhahn 2009). However, the term also was used to describe other theorists’ ideas (e.g., Medler 1998), and Thorndike did not attempt to popularize this view as a distinct school of thought (Joncich 1968).

## Applications to Education

Thorndike’s appointment to a faculty position at the Teacher’s College at Columbia University unsurprisingly caused a shift in his interests. Thorndike observed how much of educational practice depended on tradition and assumption

rather than on science. As was the case with the field of animal learning, he held a conviction that it was possible to do better. Therefore, Thorndike began to focus on how psychology informed education. Thorndike (1906) wrote:

Anyone of good sense can farm fairly well without science, and anyone of good sense can teach fairly well without knowing and applying psychology. Still, as the farmer with the knowledge of the application of botany and chemistry to farming is, other things being equal, more successful than the farmer without it, so the teacher will, other things being equal, be the more successful who can apply psychology, the science of human nature, to the problems in school. (p. 10).

Thorndike identified many ways in which education could be improved. He was critical, for example, of the lecture style of teaching, writing, “The commonest error of the gifted scholar, inexperienced in teaching, is to expect pupils to know what they have been told. But telling is not teaching” (1912, p. 61). He also argued that lectures limit education to what students can be told or shown. Another problem was that lectures did not promote critical reasoning; instead:

[Teachers] frankly present the student with conclusions, trusting that he will use them to learn more. They ask of him only to attend to, and do his best to understand, questions which he did not himself frame and answers which he did not himself work out. They try to give him an educational fortune as one bequeaths property by will. (Thorndike 1912, p. 188).

Another area in which Thorndike felt that education could be improved concerned the transfer of learning from one situation to another or one task to another. Thorndike felt that transfer of learning shouldn’t be assumed. Instead, transfer occurs only to the extent to which one situation resembles another. If the tasks students are asked to complete in school are unlike the “real-world” tasks to which learning must be applied, then transfer will likely be poor. Thorndike observed that a teacher could better prepare students by teaching students skills in school that closely match the skills those students are expected to need in the future. Similarly, Thorndike recommended that the problems students are given in the classroom should resemble the problems they will face in the real world. In line with

these views, he was a proponent of apprenticeships, internships, and other forms of experiential learning.

Thorndike frequently referred to the principles of learning when making recommendations concerning educational practice. For example, Thorndike viewed much of learning in S-R terms and believed a teacher can help a student connect a certain situation to the appropriate response by ensuring that the student is ready for the connection to be made and by ensuring that the appropriate response is followed by satisfaction to the learner.

## Revisions to Connectionism

Thorndike continued to study learning throughout his career and over time came to be influenced by the work of Pavlov, Tolman, and other learning theorists. Eventually, he began to revise portions of his theory and propose additional factors in learning (cf. Olson and Hergenhahn 2009; Thorndike 1932). The most notable revisions involved the law of effect and the law of exercise. Thorndike revised the law of effect to state that rewards strengthen a connection, while punishment has no comparable effect (indeed, may have no effect on the strength of a connection). The law of exercise lost its status as a major component of learning. Instead, Thorndike concluded that neither use nor disuse may have much of an effect on the strength of an S-R connection.

Among the new principles added to connectionism were belongingness, impressiveness, and polarity. Belongingness is concerned with whether there is by nature or experience a tendency to perceive one stimulus as “belonging” in some way to some other stimulus or to some response, in which case a connection more readily occurs. Impressiveness is roughly concerned with how intensely the stimulus affects the learner. A bright light is relatively “impressive” as are more emotionally charged words, such as “love,” “kiss,” “insane,” and “vomit” (Thorndike 1932, p. 131). Thorndike found that using more impressive stimuli leads to stronger S-R connections. Polarity is concerned with the normal sequence in which a series of actions are

performed. Each step in the sequence is associated with the step that precedes it; there is little “backward association” among the steps (Thorndike 1932, p. 152). Therefore, for example, it is easier to perform a skill in a forwards manner than in a backwards manner (e.g., a musician playing the notes in a song).

## Conclusion

Thorndike began his research in an era in which claims about animal learning commonly rested on isolated cases. Thorndike pointed out:

Dogs get lost hundreds of times and no one ever notices it or sends an account of it to a scientific magazine. But let one find his way from Brooklyn to Yonkers and the fact immediately becomes a circulating anecdote.

Thorndike sought to replace this approach with a systematic study of learning and behavior under controlled conditions. He considered the history of the subject, attempted to control motivation, and repeated observations by using multiple subjects and multiple conditions. In his experiments, he wrote:

...the work done by one investigator may be repeated and verified or modified by another. No personal factor is present save in the observation and interpretation. ... The curves showing the progress of the formation of associations, which are obtained from the records of the times taken by the animal in successive trials, are facts. ... They are absolute, and whatever can be deduced from them is sure. (Thorndike 1898, p. 7)

Thorndike’s puzzle-box experiments lacked methodological rigor and employed primitive analyses compared to modern research (Chance 1999), nevertheless they represent a seminal moment in the study of animal learning and behavior. At the time he began his research, it was unclear to what extent animal behavior was the result of instinct or reason. He discovered that animal learning was best described by something else entirely: trial and error learning, or rather, “trial and accidental success” (Thorndike 1898, p. 105). He also either discovered or anticipated many other concepts important to the psychology of learning or cognitive psychology; for example,

“associative shifting” anticipates the discovery of shaping procedures, the “law of assimilation” describes stimulus generalization, the principle of “the prepotency of elements” describes a form of selective attention and claims that “readiness” can be partly innate anticipates the discovery of biological preparedness in learning.

By taking a science-based approach to the field of education, Thorndike demonstrated how one could study best practices in teaching and free the field of education of questionable assumptions about student learning.

It is difficult to overstate Thorndike’s importance to the psychology of learning, especially during the first half of the twentieth century. For example, B. F. Skinner admired Thorndike and saw himself as continuing the work Thorndike had started (Joncich 1968, p. 506). Perhaps none were as complementary as Tolman, who wrote:

The psychology of animal learning—not to mention that of child learning—has been and still is primarily a matter of disagreeing with Thorndike, or trying in minor ways to improve upon him... all of us in America seem to have taken Thorndike, overtly or covertly, as our starting point. And we have felt very smart and pleased with ourselves if we could show that we have, even in some very minor way, developed new little wrinkles of our own. (Tolman 1938, p. 11)

## EEG

David Luque  
UNSW Sydney, Sydney, NSW, Australia

## Synonyms

[Electroencephalogram](#); [Electroencephalography](#)

## Definition

EEG stands for both electroencephalogram and for electroencephalography. While electroencephalography is the name of a *test* (see below), electroencephalogram is the resulting signal from that

test. Electroencephalography measures the electric field that is naturally elicited by brain activity, usually recorded at scalp level. However, in animal research and in some medical applications, invasive intracranial recording is sometimes used.

## What is Registered by the EEG Test?

Neurons communicate each other through so-called nerve impulses or *action potentials* (see ► [“Action Potentials,”](#) this volume). EEG signal is rarely produced by these action potentials themselves. On the contrary, EEG electrodes register the electrical activity produced by the chain of biochemical processes originated as a consequence of the *action potentials*. Without getting in too much detail, action potentials produced neurotransmitters that bind to receptors, what changes the extra- and intracellular ionic flow of neurons, in what is known as *postsynaptic potentials*. During *postsynaptic potentials*, the ionic concentration outside neurons becomes unevenly distributed, what makes them a dipole with positive and negative charged ends (or poles) (for more detail see Buzsáki et al. 2012). Dipoles generate an electromagnetic field. EEG electrodes can detect this electric signal, while *magnetoencephalography* devices are able to detect the magnetic field.

The electric signal elicited by one neuron is too weak to be detected by EEG, especially when the EEG signal is noninvasively measured at scalp level. Only when a large number (millions) of neurons are active at the same time, the sum of all these small electric fields forms a dipole strong enough for being detected by the EEG electrodes placed at the scalp. Importantly, electric fields only add each other when they have the same orientation (otherwise, they cancel each other). For this reason, EEG signal is produced by brain structures in which neurons share the same spatial alignment. Brain areas with such regular structures are mostly in the cerebral cortex. For this reason, the EEG test is useful for the study of cortical brain activity, and it is considered not suitable for the study of subcortical regions (see Luck 2005). Thus, in brief, we could say that the

EEG test measures the electric field produced by the sum of millions of postsynaptic potentials in the cerebral cortex.

## Advantages and Disadvantages of the EEG Test

One of the greatest advantages of using EEG is its great temporal resolution, in the range of the millisecond (or even better for intracranial measurements). Therefore, the use of EEG is especially appropriate if you are interested in knowing *when* certain brain activity occurs (see ► [“Event-Related Potentials \(ERPs\),”](#) this volume). However, EEG spatial resolution is low as compared with other neuroimaging techniques (e.g., fMRI). The reason for this is that, given a specific EEG distribution at scalp level (i.e., a 2D map of differences in voltage), there are an infinite number of possible combinations of dipoles (in a 3D space) that could cause it. This has been known as the *inverse problem in EEG*, and, although several mathematical tools have been proposed to solve it (see Grech et al. 2008), it is still advisable to combine EEG with other neuroimaging techniques (e.g., fMRI) if you are interested in the neural generators of the EEG signal. The other important limitation of EEG is that it cannot register neural activity from subcortical brain areas.

However, the EEG test has advantages that make it very popular in both research and medical contexts. The EEG test is relatively inexpensive and is noninvasive, and it can be easily combined with other techniques, such as eye-tracking or fMRI.

## Most Common Uses

EEG is used for both research and medical purposes. In research, EEG is widely used in the form of *event-related potentials* (see ► [“Event-Related Potentials \(ERPs\)”](#)). In addition, sleep research has been greatly benefited of the use of EEG. For instance, EEG is used to discriminate and study sleep stages. In medical context, EEG is

used in several clinical circumstances, for instance, for epilepsy diagnosis and monitoring and for monitoring brain activity of patients in a coma or a vegetative state.

<sup>3</sup>Departamento de Psicología, Facultad de Ciencias Sociales, Universidad de Chile, Santiago, Chile

## Definition

An Effect Size (ES) is a statistic or a parameter that reflects the quantitative magnitude of a phenomenon or the intensity of an association among two variables in a meaningful way. Furthermore, it is focused on describing the size of the difference

or the association rather than confounding this with sample size (Coe 2002). It is precisely for this reason that today there is a clear push for ES to be reported and used for discussing the importance of the results obtained in research studies (Kelley and Preacher 2012). For example, quantifies how fast a rat solves a maze when an experimental training is used vs. a control group.

## Introduction

Traditionally, statistical analyses in scientific research have taken the form of significance tests. Fisher developed the Null Hypothesis Significance Testing (NHST), guided by the idea of falsifying the scientist's hypothesis, in line with Popper's falsificationism. Although at first he set the  $\alpha$  at .05 (i.e., the probability to make a false positive, point out that there is an effect when there is not), later he argued against the idea of using threshold probabilities and pointed out that probabilities can be used as a continuous measure of strength of evidence against the null hypothesis (Fisher 1973); nevertheless, he was mistaken as it does not say anything about the value or the magnitude of that evidence.

Additionally, null hypotheses are almost always false (Kirk 2015), i.e., although trivial, a variable always has an effect over others. Therefore, trivial differences can be labeled as statistically significant with a big sample size and conversely, a limited sample size can output a nonsignificant result, although the difference exists. These lead researchers to control for type I error (reflected in  $\alpha$ ), neglecting type II error (i.e., a false negative, not finding an effect that exists; Kirk 2015).

Finally, Null Hypothesis Significance Testing approach goes in another direction than scientific inference (Kirk 2015). The first one is concerned with the probability of obtaining a set of data (or more extreme) if the null hypothesis is true, while the latter has to do with the probability that the null hypothesis is correct based on available data. These two probabilities rarely coincide (Falk 1998).

Criticisms about the Null Hypothesis Significance Testing have led quantitative psychologists

to search manners to complement it. One of them is the effect size. Despite the successive calls from the American Psychological Association (APA; e.g., APA 2020) encouraging its use, the reporting of ES keeps being limited (Barry et al. 2016).

In the literature, there are several definitions of effect size (we presented a general one above). For instance, for Kelley and Preacher (2012) is a quantitative reflection of the magnitude of a phenomenon used for addressing a question while for the APA and the AERA (American Educational Research Association) is a population-based parameter that can be estimated from samples with uncertainty and reflects the index of the effect or the relation between variables (Peng and Chen 2013). According to Kirk (2015), it can be a statistic or a parameter that allows to quantify the size of a phenomenon of interest in an interpretable way. As can be noticed, APA and AERA definition emphasizes the function while others the statistic to be used. Nevertheless, all of them point to the same idea.

Commonly, it has been pointed out that ES are free-scale measures. That is not totally true because some are standardized while others don't. Using a standardized ES allows you to compare data from different scales of the same conceptual variable. The use of an effect in the original metric is easier to interpret.

As has been noted above, hypothesis testing is very sensitive to the sample size. In contrast, ES does not depend on the sample size; however, it can be better estimated with bigger sample sizes.

ESs are very useful in behavioral science. Besides its uses as a report of the quantitative magnitude of a phenomenon, it also allows calculating the required sample size to achieve an acceptable power (i.e., the capacity of the study's to find the phenomenon, inversely related to type II error), integrate the literature from different experiments and reports about the same question by meta-analytic techniques, and determine the practical significance of research results.

## Effect Size Estimates

There are a lot of effect size measures and most of them can be grouped in two categories:

differences between groups (the *d* family) and measures of association (the *r* family).

### Difference Between Groups

The procedures that belong to this family estimate difference of parameters like differences in means or proportions. The group's comparison can be done on continuous and dichotomous variables.

#### Continuous Data

The first effect size measure explicitly labeled as such is part of this family and was introduced by Cohen (1969) is the parameter  $\delta$ , given by:

$$\delta = \frac{\mu_E - \mu_C}{\sigma}$$

where  $\mu_E$  stands for the population mean of experimental group and  $\mu_C$  is the population mean of the control group.  $\sigma$  represents the common population standard deviation. Given that the numerator can be influenced by the scale of measure of the means, is divided by  $\sigma$  to rescale it in units of the amount of error variability in the data (Kirk 2015). For that reason, it is recognized as a standardized measure.

To estimate  $\delta$ , Cohen's *d*, Glass's *g*, and Hedges's *g* had been developed. They have in common that are standardized ES estimators and assume normality of the distribution of data and homoscedasticity (i.e., similar variance between the groups; Peng and Chen 2013; Kirk 2015).

Of these, Cohen's *d* is perhaps the most commonly reported. It ranges from negative infinity to infinite, where the sign – positive or negative – indicates the direction of difference between groups. It is calculated as follows:

$$d = \frac{\bar{X}_1 - \bar{X}_2}{\sigma_{\text{pooled}}}$$

where  $\bar{X}$  stands for sample mean of each group and  $\sigma_{\text{pooled}}$  is calculated as:

$$\sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2}}$$

With  $n$  = sample size and  $s^2$  is the variance statistic.

Cohen (1988) proposed that Cohen's  $d$  of 0.2 is a small effect size, while 0.5 and 0.8 are medium and large, respectively. However, an effect size must be interpreted as small or large linked to the research area, the methods employed and the outcome.

Despite its widespread use, Cohen's  $d$  has some problems. In the first place, it is a biased estimator of  $\delta$ . Also, the estimation of  $\sigma$  depends on the groups size. In the third place, it must be said that if the population variances are not equal, it is problematic estimate  $\delta$  from Cohen's  $d$  because the parameter itself is undefined. Finally, this estimator is sensitive to outliers.

Another estimator of  $\delta$  is Hedges  $g$ . It only introduces a little change in the way of estimating  $\sigma_{pooled}$  respect to the formula just presented: to  $n_1 + n_2$  is subtracted the value of two (i.e.,  $n_1 + n_2 - 2$ ; Hedges 1981)

Finally, we present Glass's  $g$ , which was developed for meta-analysis in the context of an experimental study with one control group and an experimental one. Glass reasoned that comparisons of different experimental groups with control could lead to differing estimates of  $\sigma_{pooled}$ . Due to this, instead of dividing by  $\sigma_{pooled}$  as in Cohen's  $d$ , the mean difference is divided by control's group sample standard deviation (Glass 1976). Depending on the research design, it could be estimating different parameters, so researchers must be cautious. It is traditionally recommended when the homoscedasticity assumption is violated.

### Dichotomous Variables

When the groups are compared on two-level variables (e.g., solve vs. fail to solve a recognition task), comparisons can be based on the probability that the members of a group will be classified in one of the categories.

The two measures that we present here, risk ratio and odds ratio, compare how possible is the occurrence of an event in one group relative to the other group. The first one understands likelihood in terms of probabilities while the second does it in terms of odds. These indexes will be explained using a fictional example.

Imagine that a group of researchers conduct an experiment to learn if the maternal consumption

**Effect Size, Table 1** Number of descendants able to solve a memory task

|        | Solve the task | Fail to solve the task | Total |
|--------|----------------|------------------------|-------|
| THC    | 27 (0.9)       | 3 (0.1)                | 30    |
| No-THC | 7 (0.2)        | 28 (0.8)               | 35    |

*Note:* In the table is shown the number of descendants of mothers treated with Tetrahydrocannabinol (THC) and non-treated rats able to successfully solve an object recognition task and those who failed.

of THC affects the recognition ability of its descendants (measured in an object recognition task, widely used in the study of rodentia memory and the study of memory and learning other species). They obtain the following results, expressed as row data (probabilities) (Table 1):

The risk ratio is calculated dividing the probability of the outcome in one group ( $p$ ) over the probability of that outcome in the other group. In this example, the outcome is the number of rats that solved the task and the groups are THC (i.e.,  $p$ ) and No-THC (i.e.,  $q$ ). In this case it is 4.5.

To calculate the odds ratio, the other measure of this group presented here is needed to compare the odds of certain outcome for each group. The formula is as follows:

$$OR = (p/(1 - p))/(q/(1 - q))$$

Replacing the values with the outcomes from Table 1, we have:

$$OR = (0.9/(0.1))/(0.2/(0.8)) \Rightarrow 36$$

If the result of this division were smaller than one, then the outcome is more likely in the second group. If it is one, then there is no difference. If it were larger than one, then the outcome is less likely in the second group. In this case, the odds ratio is 36, which means that the likelihood of descendants able to solve the task is minor in the group treated with THC.

### Association Measures

The ES of this family includes measures of association among two or more variables.

Pearson's  $r$  (developed in 1896) is probably the most known and several of the other members of this groups are variations of  $r$ . Indicates the degree of linear association between two variables and ranges from  $-1$  to  $+1$ , where  $|1|$  means perfect association. It must be taken account that the scale is not linear (e.g., 0.2 is not twice 0.1). When it is squared, we have the coefficient of determination used in bivariate regression analysis and indicates how much of the variance of one variable can be attributed to the other. It is measured in terms of percentages.

In the context of multiple regression analysis, when one variable can depend on a set of predictors, it is used the coefficient of multiple determination ( $R^2$ ). However, it can be inflated through the sample size and the number of predictors in the model. One alternative developed to deal with this is the adjusted  $R^2$ .

$\eta^2$  or correlation ratio also can correct the resulting inflation of  $R^2$ , although partially. It is more common in psychology that  $R^2$ , allowing to know how many of the dependent's variable variance is accounted by the group membership of the subjects.  $\eta^2$  is also associated to – one-way – Analysis of Variance (ANOVA; i.e., there are more than two groups).

Finally, we present the Cohen's  $f$ . It is used in the context of multiple regression but also in ANOVAS as  $\eta^2$ . In the last case, it can be considered as an extended version of Cohen's  $d$  and it is used to measure the dispersion of means among three groups or more.

## Reporting and Interpreting ES

Although standardized effect size measure makes easier the processes of meta-analysis and power analysis (for example, Cohen's  $d$  can be transformed to Pearson's  $r$ ), the literature suggest the use of ES in the original metrics of the variables in the context of primary research. Both may be useful.

It may be obvious, but the ES reported must be specified. Also, given the lack of agreement on names for estimates of  $\delta$ , for example, its

suggested to inform how ES was calculated (Appelbaum et al. 2018).

Additionally, it is recommended to provide a confidence interval (Steiger 2004). This allows to quantify the accuracy of the point estimate. This must be considered when interpreting. The wider the confidence interval, less mature is a research paradigm. Thus, the research and historical context must be taken account in the interpretation.

## Definition

Egalitarianism is a term used variously in political philosophy, sociology, anthropology, and evolutionary psychology to describe socially organized groups that do not possess hierarchies of universal dominance by a leader or ruling set over all of the remaining members (Fried 1967; Boehm 1999). This entry focuses on anthropological and evolutionary psychological research on the presence and structures of egalitarianism in both human and nonhuman primate groups. It does not address philosophical arguments on egalitarianism.

## Tolerance and Egalitarianism in Nonhuman Primate Societies

To this date, Flack and de Waal's taxonomy of power (2004) in nonhuman primates is considered by some researchers (cf. Watts 2010) as the most comprehensive attempt to classify the distribution of power, and its correspondent political behavior, in societies of nonhuman primates. According to their perspective, dominance style is classified into (1) despotic, (2) tolerant, (3) relaxed, and (4) egalitarian. The distribution of social power associated with a despotic style is uniformly distributed and often found in hierarchical social systems where access to resources is specified by the individuals' social rank. In this type of political organization, coalitions and alliances tend to reinforce the hierarchical system. Alternatively, the distribution of power in societies displaying a tolerant dominance style is relatively equal among most individuals. This dynamic, however, does not entirely preclude some group members from exerting greater social power over others. Tolerance is found in constrained political systems where leveling coalitions, policing, and mediation regulate the frequency and intensity of internal conflict. The distribution of power in societies exhibiting a relaxed dominance style is ephemeral based on occasional differences in individuals' social power. Group members live under an equal outcome system enforced by several coalitions destined to protect and mediate the relations between subordinate and dominant conspecifics. Hence, third-party policing facilitates the equal distribution of resources. Lastly, in egalitarian organizations, some group members act more influentially or powerfully than others, with most individuals not differing across time in their social power. An egalitarian style is often associated with an equal opportunity political system and with the punishment of free riders and non-punishers.

Other authors have also developed similar classifications. Plavcan (2004), for example, ranked numerous extant primate species based on the reported intensity and frequency of intrasexual competition. The author operationalized the intensity dimension as the degree to which individuals

live under strict social hierarchies being based on the outcomes of agonistic interactions and the degree of social tolerance. Under this scheme, species are classified as featuring either low or high intensities of conflict. Alternatively, the dimension of frequency of conflict entailed the probability of intrasexual agonistic interactions based on the number of breeding individuals of the same sex. Hence, the author assigned primate species living in societies with multiple adult males as high-frequency taxa. In contrast, low-frequency primates featured a single breeding male or had a short mating season with several males competing with each other for copulations. Consequently, Plavcan generated a 4-point competition scale based on the combination of intensity and frequency of conflict (level 1, low intensity and low frequency; level 2, low intensity and high frequency; level 3, high intensity and low frequency; and level 4, high intensity and high frequency). Plavcan's scale featured considerable convergent validity with canine size dimorphism, a metric often interpreted as a proxy for the magnitude of intrasexual competition. The author's evaluation revealed that only a small number of primate species fall under the first competition level, whereas the vast majority of primates live in societies featuring some degree of social despotism. Evolutionary researchers, such as Boehm (1999) and Turchin (2016), have developed theoretical and mathematical models for understanding the evolution of egalitarianism in human societies. Per Boehm (1999), prehistoric human communities evolved an array of social mechanisms leading to the establishment of an antihierarchical structure wherein a large coalition holds upstarts and despots at bay.

## Egalitarianism in Human Societies

Prior to a time approximately 12,000 years ago, humans were essentially egalitarian in political structure. Human egalitarianism is commonly found in bands or tribal societies but is often starkly contrasted by despotic behavior. The presence of egalitarianism in a society implies relatively universal equality in the authority of

individual members in relation to others. It is not, however, associated with other potentially unequal traits separating group members. Early work on egalitarianism by Fried (1967) noted substantial individual differences in male strength, prestige, influence, and even authority. Although those differences were openly viewable and acknowledged by other group members, in egalitarian societies, Fried observed that they do not culminate in an organized hierarchy that preferentially benefits individuals with such advantages (Boehm 1999).

Several authors have proposed different explanations of the social and environmental roots of egalitarianism in humans. Sharp (1973), studying Australian Aboriginal societies, proposed the presence of intertwined dominance-submission networks that suppress the possibility for hierarchy. These networks ensured that every male was both submissive and dominant to some other males, thus promoting egalitarianism (Boehm 1999). Turnbull (1965) found, when studying Mbuti Pygmies, that constant demographic modifications to band composition appeared to decrease the effectiveness of control by potential authority figures. Gluckman (1965) pointed to specialization as the leading cause, claiming that nonspecialized systems of production would decrease hierarchy, noting that most nomadic foraging tribes are generalists. Lastly, Slobodin (1969) and Cashdan (1980) both claim that nomadic forms of subsistence place limits on the ability of the group to accumulate vast amounts of resources, acting as a leveling mechanism on social inequality.

Though each of the theories above successfully presented evidence corroborating their view, Guenther (1991) pointed out the heavily localized bases of these theories, noting that none attempted to make universal claims beyond the tribe or band they were studying. Boehm extends Guenther's critique by describing these theoretical viewpoints as not only limited in scope but also sometimes contradictory with observations from nonliterate agricultural societies who are not nomadic, do not practice widespread sharing of food and resources, have many material goods, are economically specialized, and exhibit stability in

group demographics. In such groups, strikingly similar forms of egalitarianism have been observed to that normally remarked upon in the cases of hunter-gatherer societies. Alternatively, Fried (1967) and Boehm (1999), among others, suggest a theoretical importance for a range of leveling mechanisms in explaining egalitarianism. Boehm (1999), for instance, developed a taxonomy of antiauthoritarian sanctions destined to curb the rise of despots and upstarts. Per Boehm, public opinion, criticism, and ridicule operate as mild forms of punishment where the goal is for the target to feel ashamed and rectify his behavior. Alternatively, individuals may also disregard the wishes of upstarts attempting to coerce other group members or abandon the community as a form of avoiding a confrontation with the despot. If, however, the defector's transgressions are thought to threaten the rest of the community members' livelihoods directly, the group can adopt more severe sanctions, including expulsion or execution. In contrast to other forms of punishment, the decision to execute a defector requires the upstart's kin and allies to either participate or at the very least agree with the community's determination. Carrying through an execution without the consent of friends and relatives of the target may lead to a chronic state of internal blood feuds jeopardizing the group's cohesion. It is worth noting that the effectiveness of these mechanisms varies depending on the community's size and the probability of recurrent interactions. Hence, the larger the group and the greater the anonymity among co-residents, the less likely sanctions such as criticism and ridicule will successfully maintain within-group cooperation.

In studying egalitarian societies, Fried noticed the presence of multiple high-status positions replacing that of a single leadership role. This was present across a range of roles, from hunters to shamans, and resulted in a dilution of competitiveness that allowed rivalries formed over status to be resolved in non-zero-sum ways. The study of human universals has continued as a necessary entry to the topic of egalitarianism and its evolutionary significance. Boehm (1999) combines the often separated universals of an innate tendency toward domination and another toward avoiding

being dominated. The favoring of anti-authoritarian political tactics is one such form of avoidance. The second tendency is one that promotes the formation of egalitarian structures. The first does not promote such structures but is not always actively opposing them either. Further, Boehm views such universals as nested within forms of cultural conditioning that can substantially alter their expression. Both individuals and groups, depending on the structure of decision-making in a society, can alter their environments through niche construction, favoring either more egalitarian or more autocratic structures. One possible interpretation of Fried's (1967) and Boehm's (1999) works concerns the fact that forms of cultural conditioning involving the surrounding physical ecology, which controls the degrees of specialism and generalism present in a society, can act as a leveling mechanism. As a result, human egalitarianism differs from nonhuman forms in several ways, which will be discussed further here, most notably avoiding relaxed structures.

## Discussion

Egalitarianism is studied in numerous social contexts. In nonhuman primates, egalitarian social structures strongly influence subsequent behaviors, sometimes species-specific ones, in intrasexual competition and group power relations more generally. In egalitarian political systems, as opposed to despotic ones, individuals distribute power evenly throughout the social group, with punishment expected for those who do not cohere. Additionally, punishment is expected from those who do, as members who do not punish nonconforming members can also be viewed negatively. Although nonhuman primates generally live in systems with some degree of despotic rule, those that do live in egalitarian structures appear to follow these general rules uniformly. Human egalitarianism, however, does differ from nonhuman forms through its stability in expression. In particular, human egalitarianism is marked by universal patterns that appear to be observable exclusively in human social groups

and not other primate species. Additionally, a substantially larger literature has been amassed on human egalitarianism than nonhuman egalitarianism because of the political and sociological emphasis placed on the concept by numerous theorists and philosophers. These approaches have differed from standard operational uses of the term in the empirical sciences that culminate in the observations documented here.

## Egocentric Frame

Sylvain Fiset  
 Université de Moncton, Campus d'Edmundston,  
 Edmundston, NB, Canada

## Synonyms

[Linear egocentric spatial information](#)

In animal literature, egocentric frames of references have historically been associated with the concept of response learning. However, unlike egocentric information, which is a mental representation of space, response learning is the learning of a motor act. For instance, response learning has been used to describe animal spatial learning abilities in various experimental conditions like the T-maze, in which they learn to discriminate the right and left arms of the maze based on position of their body axis (*e.g.*, see Blodgett and McCutchan 1947). Egocentric spatial information is a much more complex form of spatial cognition than response learning and should be dissociated from it. More specifically, an egocentric frame of reference refers to the directional information derived from the spatial coordinates of an organism within its surrounding environment (Bremner 1998; Fiset et al. 2006). The simplest form of egocentric spatial information is known as linear egocentric information (Fiset and Doré 1996; Fiset et al. 2000), which is used by animals to plan and maintain a single direct trajectory towards a specific location. Dead reckoning, also known as path integration, is a more sophisticated form of an egocentric frame of reference (Étienne and Geffery 2004; Wallace et al. 2002). Animals use this to keep track of their displacements and reorientations through space by encoding vestibular information to return to a desired location. The current definition of an egocentric frame of reference is limited to the linear form of egocentric information.

A linear egocentric frame of reference is best described with a Cartesian coordinate system. In a Cartesian plane, a vector is a line between two points in space: its length represents the distance and its angle represents the direction. Thus, a linear egocentric frame of reference can be defined as a vector between two points in space (see Fig. 1): one point ( $x_1, y_1$ ) is the current spatial coordinate of the animal, and the second point ( $x_2, y_2$ ) is the spatial coordinate of the target location. However, before determining a vector in the direction of the target position, an animal must first establish its current position relative to its own spatial location. This can only be done if the animal constructs a cognitive map of its environment. The concept of a cognitive map (see Gallistel 1990) suggests that an animal encodes

and uses the geometric components of distance and direction (vectors) between landmarks to navigate. Thus, the animal positions itself within its cognitive map by encoding a series of vectors emanating from its current location and pointing to some prominent landmarks (see Landmark 1 and Landmark 2 in Fig. 1). By establishing its position relative to these landmark vectors, the animal now has the liberty to reorient itself relative to its own position without losing track of its position or of the desired location. From these landmark vectors, the animal then determines a directional vector from its current position to its target location. Once this directional vector has been specified, the animal can mentally determine the angular deviation ( $\theta$ ) and the distance between its own spatial coordinates in the environment and those of the target location. It is this last form of spatial representation that corresponds to linear egocentric spatial information.

It is also worth mentioning that egocentric frames of reference are highly vulnerable. Indeed, if the directional vector is broken due to environmental circumstances, such as strong winds that shift an animal off course or some obstacles must be bypassed by the animal, it is highly probable that the animal will lose track of its direction and distance. Nevertheless, when environmental conditions are stable, the use of an egocentric frame of reference is well adapted and suitable.

From a comparative perspective, the domestic dog is a nice model to illustrate the use of a linear egocentric frame of reference in animals. Indeed, a few studies have shown that the domestic dog strongly relies on a linear egocentric frame of reference to search for objects (conspecific, toys, prey) that it has seen disappear (see Fiset et al. 2000, 2006). In these studies, the dogs' task was to search for an attractive object they have seen disappear behind one of the screens placed in front of them. After the disappearance of the object, an opaque panel was introduced in front of the dog for a short retention interval (*e.g.*, 10 s). During this interval, the walls of the testing room as well as the screens were systematically shifted to the right or to the left. At the time of searching, although, from the dog's perspective, the visual properties of the room had drastically changed and that the dogs' body/head orientation did not

**Egocentric Frame, Fig. 1** Illustration of an egocentric frame of reference with a Cartesian coordinate system.  $(x_1, y_1)$  represents the coordinates of the encoding position of

the animal (a dog), and  $(x_2, y_2)$  represents the coordinates of the target location.  $\theta$  represents the estimated angle of the directional vector

correlate with the hiding position, the dogs systematically searched at the initial hiding location. These results therefore support the hypothesis that the domestic dog encodes and uses a directional vector associated with an egocentric frame of reference for finding hidden objects. Additional studies (Fiset 2007, 2009) have also revealed that the domestic dog positions itself in the environment by encoding the distance and the direction from local and global landmarks. These later studies therefore suggest that the domestic dog encodes and uses a metric cognitive map, which is used to determine its egocentric frame of reference.

## Definition

Insemination package of sperm and other compounds produced by the male to facilitate transfer of sperm to the site of fertilization

## Introduction

An ejaculate is composed of male genetic material housed within sperm cells and fluids containing chemical compounds that improve male fertilization success. Sperm is produced in the testes and travels out of the male's body through a system of ducts connected to the accessory reproductive glands (ARGs). The accessory reproductive glands add fluids to the ejaculate for sperm nourishment and protection while inside the female reproductive tract.

## Sperm Production

Spermatogenesis, or the process of sperm production, occurs within microscopic tubules within the testicles. Mature sperm cells develop from

spermatogonia, the undifferentiated male germ cell, and are matured and stored within the male reproductive tract prior to ejaculation. Sperm cells are haploid, meaning they contain only half of the genetic material present in all other cells in the body. As such, sperm cells are recognized as “nonself” and targeted by the immune system. In order to avoid this unwanted immune response, males down-regulate immune activation in the testes through the excretion of androgens. Immune compromised males have less scope for immune suppression and will therefore have compromised sperm production, making sperm quality a reflection of male health (Folstad and Skarstein 1997).

## Sperm Morphology

Although sperm size and shape is remarkably diverse both within and between taxa, most sperm cells are generally composed of four main constituents: the acrosome, nucleus, mitochondria, and flagellum. Sperm are generally minute compared to the size of the egg and typically do not contribute nutrition to the zygote. A proportion of ejaculates typically contain non-viable, morphologically aberrant sperm. The proportion of morphologically normal sperm in an ejaculate can be highly influenced by the environment (e.g., chemical pollutants), pathogens, and degree of sperm competition (Pitnick et al. 2009).

Sperm heteromorphism, typically in the form of dimorphism, occurs when males produce morphologically discrete types of sperm cells. This occurs across a wide taxonomic range and generally results in a genetically functional “eusperm” morph and a nonfertilizing “parasperm” morph (Pitnick et al. 2009). Parasperm are hypothesized to improve fertilization success in many different ways, such as by transporting eusperm, provisioning eusperm, assisting in eusperm capacitation, disabling the sperm of previous mates, or delaying remating in the female, though there is limited evidence supporting any one hypothesis. At present, there is only a rudimentary understanding of the adaptive value of diverse sperm morphologies.

## Accessory Reproductive Glands

The composition and organization of male accessory reproductive glands (ARGs) varies both within and between classes of organisms, but collectively they provide fluid to transport and nourish sperm on their journey to the egg. In internally fertilizing species, these fluids are generally alkaline to buffer the sperm in the acidic environment of the female reproductive tract and commonly possess a mixture carbohydrates, lipids, and amino acids for sperm nourishment (Gillott 2003). In addition to its role in transporting and nourishing sperm, ARG fluids can also change female behavior and physiology. In *Drosophila*, male ARG fluids increase rate of female egg-laying, reduce female receptivity to further matings, and destroy the sperm of previously mated males (Chapman et al. 1995).

## Sperm Competition

Sperm competition intensity has consequences for the composition of the ejaculate, reproductive behavior, and morphology of the male. Sperm competition is the competition that occurs between sperm of different males to fertilize the same egg. Sperm competition theory predicts that when females mate with multiple males, selection would favor males producing the largest number of viable sperm. Supporting this prediction, the number of sperm contained in an ejaculate is positively associated with the intensity of sperm competition in a wide breadth of animals. Larger testes can produce sperm at faster rates and store larger reserves of mature sperm, so larger relative testes size is also consistently associated with degree of sperm competition (Møller and Briskie 1995).

In addition to sperm number, the outcome of sperm competition is also influenced by sperm form and function. Sperm length, velocity, and longevity have consequences for male fertilization success (reviewed in: Snook 2005). Species that engage in sperm competition are commonly observed to have longer sperm capable of swimming at higher velocities (Gage 1994). Sperm longevity declines with sperm length due to the

increased energy demands of a longer tail, thereby increasing the need for multiple ejaculations to ensure paternity in competitively mating species. Quality control of sperm morphology is also more subject to selection in species with intense sperm competition. In a comparative study of seven pairs of closely related insect species, the presence of sperm competition was associated with a larger proportion of normal live sperm per ejaculate (Hunter and Birkhead 2002).

Along with sperm anatomy, mating patterns have had evolutionary consequences for ARG morphology and fluid production. Species that engage in sperm competition have larger ARGs that secrete larger volumes of fluid per ejaculate. Chemicals in the seminal fluid can coagulate after ejaculation and form what are called copulatory, or sperm plugs. Tendency to produce sperm plugs is related to degree of sperm competition and is higher in species engaging in polygynandrous mating systems and lower in species engaging in polygynous or monogamous mating systems (Dixson and Anderson 2002). There are numerous hypotheses for the function of sperm plugs, including chastity enforcement, storage of sperm, prevention of sperm leakage, inducement of pseudopregnancy, and stimulation of sperm transport (Birkhead and Møller 1998). Sperm plug function is likely to vary between species, due to differences in plug density, longevity, and composition.

## Ejaculate Allocation

Though the cost of producing one sperm cell may be tiny, each ejaculate can contain millions of gametes, the production of which amounts to non-trivial energetic costs. As such, males are limited in the number of ejaculates they can produce related to the length of time it takes to restore depleted sperm reserves. This is observed in the diminished amount of both sperm and ARG fluids in successive ejaculates of a wide range of species, a condition which can persist for a considerable amount of time (reviewed in: Dewsbury 1982). Therefore, in species that engage in multiple successive ejaculations, strategic ejaculate allocation would be prudent.

Differential ejaculate allocation is observed in the context of mate quality and perceived sperm competition. Female quality, measured by body size, fecundity, or novelty, can be positively associated with the number of sperm per ejaculate (Spence et al. 2013). Perceived amount of sperm competition, manipulated through the density of rival males at the time of copulation, is also positively associated with sperm expenditure in a variety of insects, fish, and mammals (reviewed in: Parker and Pizzari 2010). For example, male Norway rats copulating in visual proximity to a rival male ejaculate significantly more sperm than those copulating with no other males present (Pound and Gage 2004).

The type of reproductive tactic a male engages in can also influence relative investment in an ejaculate. Males can ensure paternity by investing in features that prevent female copulation with other males, such as large body size and weaponry to win in competitive male interactions (bourgeois males), or males can opt out of direct competition and gain paternity through sneak copulations (parasitic males). Bourgeois males invest less in sperm quality because they experience less sperm competition than parasitic males, as is shown in Atlantic salmon, where small morph males have relatively larger testes, and produce ejaculates with a higher percentage of motile sperm that remain viable longer within the female reproductive tract (Gage et al. 1995).

## Conclusion

An ejaculate is made in the testes and accessory reproductive glands of males, is composed of male gametes and accessory fluids, and is costly to produce. Due to its integral role in reproduction, ejaculate properties are likely to be under strong selection. However, the adaptive significance of the diverse sperm morphologies observed in different species is still not fully understood. Sperm competition has marked evolutionary effects on sperm production, morphology, longevity, and allocation. The study of sperm allocation provides support for the little-studied role of male mate choice as a mechanism of intersexual selection.

## Definition

Electromagnetic (*em*) field is a property of free space which is caused due to the interaction of oscillating electric and magnetic field when an electric charge is in motion. This *em* field can be considered as a continuous field propagating like a wave at the velocity of light, carrying *em* energy.

## Introduction

Over the years, *em* waves have found applications in various fields such as wireless communications, bioelectronics, RADAR, EMI/ EMC, agriculture, remote sensing, etc. The design of the *em* devices used for such applications are based on the laws and principles of *em* waves. Within the *em* spectrum, an *em* wave is assigned different names based on their frequency of oscillation or its wavelength. Radio waves, microwaves, ultraviolet rays, X-rays, and gamma rays are the *em* waves having frequency in increasing order in the spectrum. The motion of an electron can be assumed to be in uniform electric field or uniform magnetic field or a uniform *em* field. The electric and magnetic fields which can be static or dynamic govern the *em* fields.

## History

In 1845, Michael Faraday studied the effect of magnetic field on the propagation of light and observed that there is a relationship between electromagnetism and light. It was then in the year 1873 when James Clerk Maxwell formulated the essentials of electromagnetic theory based on mathematical considerations derived from electromagnetic wave propagation and the concept of light being a form of *em* energy. During the period 1887–1891, Heinrich Hertz, a German physicist validates Maxwell's theory of *em* waves by carrying out a set of experiments. Until the development of RADAR during World War II in the 1940s, the

growth in *em* technology had not proliferated. During that period, research had started to develop RADAR in practice. Communication systems initiated to be established soon after the birth of radar systems (Pozar 2005).

## Maxwell's Equations

The discovery of *em* wave propagation by Hertz and Marconi is the basis of electric and magnetic phenomena at macroscopic level which is summarized by Maxwell (Pozar 2005; Jordan and Balmain 2013). Maxwell's work was based on empirical and theory established by Gauss, Ampere, Faraday, and others.

Electric and magnetic fields are independent of each other in static *em* fields, whereas the fields are interdependent in dynamic *em* fields, i.e., a time-varying electric field essentially includes a corresponding time-varying magnetic field. The general form of time varying Maxwell's equations or *em* field equations in phasor form

$$\nabla \times \bar{E} = -j\omega \bar{B} \quad (1)$$

$$\nabla \times \bar{H} = j\omega \bar{D} + \bar{J} \quad (2)$$

$$\nabla \cdot \bar{D} = \rho \quad (3)$$

$$\nabla \cdot \bar{B} = 0 \quad (4)$$

where  $\bar{D} = \epsilon \bar{E}$ ,  $\bar{B} = \mu \bar{H}$ ,  $\bar{J} = \sigma_s \bar{E}$ .

$\bar{E}$  is the electric field intensity (V/m),  $\bar{H}$  is the magnetic field intensity (A/m),  $\bar{D}$  is the electric flux density (Coul/m<sup>2</sup>),  $\epsilon$  is the permittivity,  $\bar{B}$  is the magnetic flux density (Wb/m<sup>2</sup>),  $\mu$  is the permeability,  $\rho$  is the electric charge density (Coul/m<sup>3</sup>), and  $\bar{J}$  is the electric current density (A/m<sup>2</sup>), due to an external field, and  $\sigma_s$  is the conductivity.  $\mu_0 = 4\pi \times 10^{-7}$  Henry/m is the permeability, and  $\epsilon_0 = 8.854 \times 10^{-12}$  farad/m is the permittivity of free space.

## EM Field in Material Media

When an electric field *E* is applied to a dielectric material, the polarization of the atoms or molecules

of the material occurs to create electric dipole moments that increases the total flux, *D*. This additional polarization vector is called electric polarization ( $\bar{P}_e$ ), and the electric flux is given as

$$\bar{D} = \epsilon \bar{E} + \bar{P}_e \quad (5)$$

The applied electric field is linearly related to the polarization in a linear medium by  $\bar{P}_e = \epsilon \chi_e \bar{E}$ , where  $\chi_e$  is the electric susceptibility and  $\epsilon = \epsilon_0 \epsilon_r$ . The relative permittivity,  $\epsilon_r$ , of the medium is complex and expressed as  $\epsilon_r = \epsilon'_r - j\epsilon''_r$ ,  $\epsilon'_r$  and  $\epsilon''_r$  being the real and imaginary parts. When an electric field interacts with a dipole, the dipole rotates to align itself according to the polarity resulting in energy loss through the generation of heat. The degree to which the dipole is out of phase with the incident electric field is a characteristic of the material and depends on the frequency of the oscillating electric field. This determines the magnitude of the imaginary part of the permittivity. The larger the imaginary part, the more is the energy dissipated. Thus, the imaginary part of the relative permittivity relates to loss in the system.

Similarly, an applied magnetic field may align magnetic dipole moments in magnetic materials producing magnetic polarization or magnetization ( $\bar{P}_m$ ), and the magnetic flux is given as

$$\bar{B} = \mu \bar{H} + \bar{P}_m \quad (6)$$

The applied magnetic field is linearly related to the magnetization in a linear medium by  $\bar{P}_m = \chi_m \bar{H}$ , where  $\chi_m$  is the magnetic susceptibility and  $\mu = \mu_0 \mu_r$ . The relative permeability,  $\mu_r$ , of the medium is complex in general and expressed as  $\mu_r = \mu'_r - j\mu''_r$ ,  $\mu'_r$  being real part, while  $\mu''_r$  is imaginary.

Equations (1) and (2) can be rewritten as

$$\nabla \times \bar{H} = j\omega \left( \epsilon' - j\epsilon'' - j \frac{\sigma_s}{\omega} \right) \bar{E} \quad (7)$$

$$\nabla \times \bar{E} = -j\omega \left( 1 - j \frac{\mu''}{\mu'} \right) \bar{H} \quad (8)$$

The terms  $\tan \delta_e = \frac{\omega \epsilon'' + \sigma_s}{\omega \epsilon'}$  and  $\tan \delta_m = \mu'' / \mu'$  describe the amount of energy supplied by an

external *em* field that gets dissipated during dipole alignment.

## Uniform Plane Waves

Considering the case of *em* phenomena in free space and solving the field equations, the following equations are obtained as

$$\nabla^2 \bar{E} = \mu\epsilon (j\omega)^2 \bar{E} = -\omega^2 \mu\epsilon \bar{E} \quad (9)$$

$$\nabla^2 \bar{H} = \mu\epsilon (j\omega)^2 \bar{H} = -\omega^2 \mu\epsilon \bar{H} \quad (10)$$

Equations (9) and (10) are known as the wave equations or Helmholtz equations. The electric field intensity or the magnetic field intensity must satisfy the wave equation.  $k = \omega\sqrt{\mu\epsilon}$  is a constant which is called as the wavenumber or propagation constant of the medium.

## Plane Waves in a Lossless Medium

$\epsilon$  and  $\mu$  are real in a lossless medium, so  $k$  is also real. Considering an electric field with no variation in  $x$  and  $y$  directions, the wave equation reduces to

$$\frac{\partial^2 E_x}{\partial z^2} + k^2 E_x = 0 \quad (11)$$

The solutions to the above equation is in the form

$$E_x(z) = E^+ e^{-jkz} + E^- e^{jkz} \quad (12)$$

where  $E^+$  and  $E^-$  are the arbitrary amplitude constants. The first term and the second represent wave traveling in the  $+z$  direction and  $-z$  direction.

The velocity of the wave at which a fixed phase point on the wave travels is called the phase velocity and is given by

$$v_p = \frac{1}{\sqrt{\mu\epsilon}} \quad (13)$$

In free space,  $v_p = 1/\sqrt{\epsilon_0\mu_0} = 3 \times 10^8$  m/s, which is the speed of light.

The wavelength,  $\lambda$ , defined as the distance between two successive maxima or minima on a wave at a fixed instant of time is given as  $\lambda = v_p/f$ .

Similarly,

$$H_y(z) = \frac{1}{\eta} [E^+ e^{-jkz} - E^- e^{jkz}] \quad (14)$$

where  $\eta = \omega\mu/k = \sqrt{\mu/k}$  is the ratio of the  $\bar{E}$  and  $\bar{H}$  fields which is known as wave impedance or intrinsic impedance of the medium. In free space,  $\eta_0 = \sqrt{\mu_0/\epsilon_0} = 377\Omega$ .  $\bar{E}$  and  $\bar{H}$  are orthogonal to each other and orthogonal to the direction of propagation ( $z$ ) and thus a transverse electromagnetic (TEM) wave.

## Plane Waves in a Lossy Medium

For a lossy medium, if it is conductive, then the field equations take the form as

$$\nabla \times \bar{H} = j\omega\epsilon \bar{E} + \sigma_s \bar{E} \quad (15)$$

$$\nabla \times \bar{E} = -j\omega\mu \bar{H} \quad (16)$$

The wave equation for  $E$  then becomes

$$\nabla^2 \bar{E} = -\omega^2 \mu\epsilon \left(1 - j \frac{\sigma_s}{\omega\epsilon}\right) \bar{E} \quad (17)$$

Comparing the above equation with the wave equation for  $\bar{E}$  in the lossless case, it is observed that the wave number  $k^2 = \omega^2 \mu\epsilon$  is replaced by  $\omega^2 \mu\epsilon (1 - j\sigma_s/\omega\epsilon)$  which is known as propagation constant ( $\gamma$ ):

$$\begin{aligned} \gamma &= j\omega\sqrt{\epsilon_0\mu_0}\sqrt{\epsilon_r\mu_r} \left(1 - j \frac{\sigma_s}{\omega\epsilon}\right) \\ &= j \frac{2\pi f}{c} \sqrt{\epsilon_r\mu_r} \left(1 - j \frac{\sigma_s}{\omega\epsilon}\right) = \alpha + j\beta \end{aligned} \quad (18)$$

$\alpha$ , is the attenuation constant which defines the rate at which the fields of the electromagnetic wave attenuates, and  $\beta$  is the phase constant representing the phase change as the wave propagates.

Considering an electric field with no variation in  $x$  and  $y$  directions, the wave equation reduces to

$$\frac{\partial^2 E_x}{\partial z^2} - \gamma^2 E_x = 0 \quad (19)$$

which has solution in the form

$$E_x(z) = E^+ e^{-\gamma z} + E^- e^{\gamma z} \quad (20)$$

The wave traveling to the positive direction has a propagation factor of the form

$$e^{-\gamma z} = e^{-\alpha z} e^{-j\beta z} \quad (21)$$

which in the time domain take the form as  $e^{-\alpha z} \cos(\omega t - \beta z)$ .

A wave is traveling in the +z direction with a phase velocity  $v_p = \omega/\beta$ , a wavelength  $\lambda = 2\pi/\beta$ , and an exponential damping factor. If the loss is removed,  $\sigma_s = 0$ , then  $\gamma = jk$ , and  $\alpha = 0$ ,  $\beta = k$ , and also

$$\gamma = j\omega\sqrt{\epsilon_0\mu_0}\sqrt{\epsilon_r\mu_r} \quad (22)$$

The associated magnetic field can be given as

$$H_y(z) = \frac{j}{\omega\mu} \frac{\partial E_x}{\partial z} = \frac{j\gamma}{\omega\mu} [E^+ e^{-\gamma z} - E^- e^{\gamma z}] \quad (23)$$

The wave impedance,  $\eta$ , is given as

$$\begin{aligned} \eta &= \frac{j\omega\mu}{\gamma} = \frac{j\omega\mu_0\mu_r}{j\omega\sqrt{\epsilon_0\mu_0}\sqrt{\epsilon_r\mu_r}} = \sqrt{\frac{\mu_0}{\epsilon_0}} \sqrt{\frac{\mu_r}{\epsilon_r}} \\ &= Z_0 \sqrt{\frac{\mu_r}{\epsilon_r}} \end{aligned} \quad (24)$$

Equation (23) can be rewritten as

$$H_y(z) = \frac{1}{\eta} [E^+ e^{-\gamma z} - E^- e^{\gamma z}] \quad (25)$$

### Plane Waves in a Good Conductor

In case of a good conductor, the conductive current is much greater than the displacement current, which means  $\sigma_s \gg \omega\epsilon$ . The propagation constant is given as

$$\begin{aligned} \gamma &= j\omega\sqrt{\epsilon_0\mu_0}\sqrt{\epsilon_r\mu_r} \left( \frac{\sigma_s}{j\omega\epsilon} \right) \\ &= (1+j) \sqrt{\frac{\omega\mu\sigma_s}{2}} = \alpha + j\beta \end{aligned} \quad (26)$$

The depth of penetration or skin depth,  $\delta$ , is that depth at which the amplitude of the fields in the conductor is attenuated to  $1/e$  or

approximately 37% of its original value, after traveling a distance of one skin depth, since  $e^{-\alpha z} = e^{-\delta z} = e^{-1}$ :

$$\delta = \frac{2}{\omega\mu\sigma_s} \quad (27)$$

For low loss microwave components, only a thin plating of a good conductor is sufficient, and most of the current flow in thin region near the surface of the conductor.

The wave impedance inside a good conductor is given as

$$\eta = \frac{j\omega\mu}{\gamma} = (1+j) \frac{\omega\mu}{2\sigma_s} = (1+j) \frac{1}{\sigma_s\delta} \quad (28)$$

### Energy and Power in em Field

As *em* waves propagate, the rate at which the energy is transferred from source to receivers is related to the amplitudes of electric and magnetic field strengths of the *em* wave. This energy is either transmitted or dissipated as loss. This rate of energy flow over any closed surface is given by Poynting theorem as

$$\bar{P} = \bar{E} \times \bar{H} \quad (29)$$

having the dimensions as watts per square meter. The direction of flow of energy is perpendicular to  $\bar{E}$  and  $\bar{H}$  in the direction of  $\bar{E} \times \bar{H}$ .

The total power flow is given by the integration of the Poynting vector over any cross-sectional surface as

$$W = \int_S \bar{E} \times \bar{H} \cdot d\mathbf{a} \quad (30)$$

### Application: Wearable Antenna

Increased mobility of human beings and requirement of good and reliable communication systems have added a new dimension to antenna design where convenience in carrying communication gadgets has acquired significant importance. Wearable computing systems are getting popular day by day due to the potential application in health

monitoring, physical training, tracking, etc. Antenna plays a major role in transmitting and receiving of data or signals among short- and long-range wireless communication systems. The design and development of low profile, light weight, low-cost, miniaturized flexible planar antennas are critical for wearable wireless communication systems (Hall and Hao 2012; Khaleel 2014). As the antenna is within a close proximity to the human body, the radiation from the wearable antenna should obey the guidelines of specific absorption rate (SAR) inside the human tissue for safety requirements. A kind of structures known as electromagnetic bandgap (EBG) structures is included in wearable antenna designs to provide isolation from the human body and reduce the SAR in the tissues (Zhu and Langley 2009; Velan et al. 2015).

An EBG structure design exhibiting an operating bandwidth of 27% and a gain of 7.8 dBi at 2.4 GHz has been proposed having low SAR values following the limit specified in the FCC regulations (Ashyap et al. 2017). The antenna which is of low profile integrated with EBG structure is capable enough to be used for wearable medical applications.

### Application: Nanocomposites for Shielding

Electromagnetic emissions are usually generated and transmitted during operation of wireless and electronic devices. Beyond a certain level, these emissions cause operational interferences and are classified as electromagnetic interferences (EMI). Growth in modern high-speed electronic devices packaged alongside the electromagnetic wave emitting sources in devices such as cellular telephony, Wi-Fi, Bluetooth, etc. are posing newer challenges for the designer. In addition, these multitudes of applications have created an even more congested electromagnetic environment leading to operational challenges of systems in close proximity (Tong 2009; Ren et al. 2016).

The em vulnerability and radiation hazard have to be controlled for obtaining an electromagnetically compatible (EMC) environment by reducing EMI. Electromagnetic shields are generally used

for sufficiently reducing EMI. Sandwich composite structures due to their strength, low weight, and good thermal insulation are being used in aerospace, automobiles, consumer industries, etc.

A sandwich structure consisting of carbon woven fabric as surface layer and a mixture of carbon particles/epoxy matrix as a binder is proposed (Novotna et al. 2018). The carbon particles were fused in epoxy in order to enhance the dielectric properties so that the electromagnetic shielding (EMI) properties and sound absorption properties of sandwich composites are improved. All of these properties are important so the application of developed composites could be beneficial in protection of equipment.

### Definition

Radiation set of different frequencies composed of waves of radio, microwave, infrared radiation, visible spectrum (or light), ultraviolet radiation, X-rays, and ray's gamma.

### Introduction

Just like several physiscal phenomena, it is not possible to define a starting point for the studies of electricity and magnetism. In 600 BC, the Greek philosopher Thales of Miletus discovered that a bar of amber would be attracted to straw if they were rubbed together. This phenomenon was later called *electricity* because the Greek word *elektron* means “amber.” There are also reports that a shepherd wearing sandals with metal nails used to feel his feet “attached” to the ground as he walked on a mountain. Once the mountain was formed by a stone known as magnetite, this effect was called *magnetism*.

In the nineteenth century, with Maxwell's equations (James Clerk Maxwell, 1831–1879), it was

shown that electricity and magnetism corresponded to the same force, that one could not exist without the other. Therefore, the study of the two forces received the name of electromagnetism. Maxwell's equation also shows that light is an electromagnetic wave, instead of the prediction of Newton's theory that light had a corpuscular character, i.e., composed of “tiny bodies,” like atoms. For more details, see “A Dynamical Theory of the Electromagnetic Field” by Maxwell (1864).

Electromagnetic waves may have different lengths (i.e., measure from a crest – the highest point of a wave) and consequently different frequencies (i.e., number of wave oscillations over time), as this relation can be seen in Fig. 1a and b. The set of these frequencies compose the *electromagnetic spectrum* (Fig. 2). Visible and invisible light are both forms of electromagnetic radiation of different wavelengths. More details about the electromagnetic spectrum can be verified in *Introduction to Electrodynamics* by Griffiths (2017).

The vision and delimitation of colors is a characteristic of each ► [species](#) eyes. For example, the spectrum range corresponding to the human eye, called *visible spectrum*, starts with violet (larger wavelengths, 760 nanometers (nm)) and ends with red (smaller wavelengths, 360 nm) (Slinye, 2016). Thus, any light with wavelengths below violet (<360 nm, e.g., ultraviolet, X-ray, gamma rays) or above red (>760 nm, e.g., infrared, microwave) cannot be seen by humans but may be possible for other animals (*for details*, see brief examples below and a chapter ► [“Evolution of Animal Color Vision”](#) by Jacobs, in this volume).

### Biological Examples

#### Humans: Visible Spectrum and Color

This range is composed of the following colors: red, orange, yellow, green, blue, and violet, with electromagnetic wavelengths from about 360 to about 760 nanometers (nm) (*for details*, see Slinye, 2016). The human eye has photon receptor cells called cones and rods that transmit information to the optic nerve, and finally to the brain, which create the image. Human vision is trichromatic, i.e., composed of three types of cones –

**Electromagnetic Spectrum,**

**Fig. 1** Relation between wavelength and frequency. (a) Shorter wavelength and higher frequency; (b) higher wavelength and shorter frequency

**Electromagnetic Spectrum, Fig. 2** The electromagnetic spectrum with different wavelengths and frequencies. Visible spectrum and biological examples of detection

longwave (L) sensitive to red (R) colors, mediumwave (M) sensitive to green (G) colors, and shortwave (S) sensitive to blue colors (B). By varying the amount of red, green, and blue light, and mainly by the interaction of these L, M, and S cones, the perception of all the colors in the visible spectrum can be possible to humans. The sensitivity of the human eye is varied according to the cone interactions, and the colors are classified according to the frequency of the light.

#### ► **Birds: Ultraviolet Vision**

Bird eyes are sensitive to different wavelengths through receptor cells, permeable lenses, and corneas. Unlike humans, avian vision is tetrachromatic: they have four single cone types that have peak sensitivities, L, M, and S, as human eyes, and ultraviolet (UV). UV is a radiation with a wavelength less than human visible light, with about 380 nm to 1 nm. This UV-sensitive cone makes birds see a greater diversity of colors than that detected by humans, and it can be used for food detecting and in feeding strategy, as in *Birds of Prey*. Also, most bird families show some UV reflectance in feathers, with an important ecological significance, acting on partner choice mechanism and communication (*for details*, see Rajchard, 2009).

#### **Bats and Snakes: Infrared Detection**

Infrared radiation is the portion of electromagnetic radiation characterized by wavelengths greater than 700 nm, or the longest wavelengths of visible light. Some snakes of the families Boidae, Pythonidae, and Viperidae have specialized receptors on the face to detect and locate ► [prey](#) and predators. Boidae and Pythonidae snakes may have scattered innervations or pits in the labial scales, and some Viperidae snakes (the subfamily Crotalinae) have only one pit on each side of the face, called pit organs. These innervations can be stimulated by infrared radiation and transmit that information to the optic tectum, by the trigeminal nerve. Snakes may create a unique image from the eyes and infrared radiation receptors. As a result, snakes can identify the size and position of prey.

Some vampire bats (*Desmodus* genus) have sensors specialized for infrared radiation in their nasal pads and nose-leaf. This sensory mechanism is connected to the trigeminal nerve, and it allows

to locate and prey on homeothermic animals, because it is possible to detect the vessels of their prey beneath thick skin. This is the main difference between bats and snakes on infrared detection; bats have ability not only to detect body heat but also for the detection of vital blood meals (*for details*, see Jones et al., 2013).

University, Varanasi, India

### **Definition**

Electrophoresis is the migration of charged particles in a liquid medium under the influence of an electrical field.

## Introduction

The term electrophoresis describes the migration of a charged particle under the influence of an applied electric field. Many important biological molecules, such as amino acids, peptides, proteins, nucleotides, and nucleic acids, possess ionizable groups and, therefore, at any given pH, exist in solution as electrically charged species either as cations or anions. Under the influence of an electric field, these charged particles will migrate either to the cathode or to the anode, depending on the nature of their net charge.

Charged molecules in an electric field migrate at a speed determined by their charge-to-mass ratio. According to Coulomb's law of electrostatics, an ion with charge  $Q$  in an electric field of strength  $E$  will experience an electric force:

$$F_{\text{electrical}} = QE$$

The resulting migration of the charged molecule through the solution is opposed by a frictional force:

$$F_{\text{frictional}} = Vf$$

where  $V$  is the rate of migration of ion and  $f$  is frictional coefficient.

Frictional coefficient depends on the size, shape, and viscosity of the solution. In constant electric field, the force on ion balances each other:

$$QE = Vf$$

So each ion moves with a constant characteristic velocity. Thus the rate of migration is directly proportional to the field strength and to the net charge of the molecule.

An ion electrophoretic mobility,  $\mu$ , is defined as the rate of migration (cm/s) per unit field of strength (volt/cm):

$$\mu = V/E = Q/f$$

So according to the equation, if two molecules have the same mass and shape, the one with the greater net charge will move faster toward an electrode (Stellwagen 2009).

When a mixture of proteins is applied to a gel and an electric current is applied, smaller proteins migrate faster than larger proteins through the gel. The rate of movement is influenced by the gels' pore size and the strength of electric field. The pores in a highly cross-linked polyacrylamide gel are quite small. Such a gel could resolve small proteins and peptides, but large proteins would not be able to move through it. SDS-PAGE is rapid, sensitive, and capable of a high degree of resolution. SDS denatures proteins, causing multimeric proteins to dissociate into their subunits, and all polypeptide chains are forced into extended conformations with similar charge-to-mass ratio. SDS treatment gives negative charge to all proteins, so the molecular weight of protein becomes the sole determinant of the migration rate of proteins in SDS-PAGE. Bands resulting from electrophoretic separation can be located by a variety of staining techniques like Coomassie staining or silver staining (Fig. 1).

## Two-Dimensional Gel Electrophoresis

In 2D electrophoresis, proteins are separated in two sequential steps: first by their charge and then by their mass. During first dimension, protein samples are run on an immobilized pH gradient gel which separates them according to their isoelectric point. In the second dimension, proteins separated according to their molecular weight by SDS-PAGE (Fig. 2).

## Native PAGE

If a particular protein (e.g., enzymes) has to be separated on the basis of its biological activity, then SDS-PAGE cannot be used as the protein is denatured by the SDS. In native gels, non-denaturing condition is used. Since all the proteins in the sample being analyzed carry their native charge at the pH of the gel, proteins separate according to their different electrophoretic mobilities.

## Electrophoresis of Proteins

### Sodium Dodecyl Sulfate-Polyacrylamide Gel Electrophoresis (SDS-PAGE)

Electrophoretic separation of proteins is most commonly performed in polyacrylamide gels.

## Electrophoresis of Nucleic Acids

Gel electrophoresis is the process by which pieces of DNA of different sizes can be resolved. An agarose or polyacrylamide gel is loaded with the DNA fragments, and current is passed through the

**Electrophoresis, Fig. 1** Schematic representation of polyacrylamide gel electrophoresis of proteins

**Electrophoresis, Fig. 2** Schematic representation of 2D gel electrophoresis of proteins

gel. Since DNA is negatively charged, it will migrate toward the positive pole. However the DNA will not migrate at the same rate. Larger

pieces of DNA collide with the gel more often and are slowed down, while smaller pieces of DNA move through more quickly. The following

**Electrophoresis, Fig 3** Schematic representation of agarose gel electrophoresis of nucleic acids

factors determine the rate of migration of DNA through agarose gels:

- Molecular size of DNA
- Concentration of agarose
- Conformation of the DNA
- Presence of ethidium bromide (EtBr) in the gel and electrophoresis buffer
- Applied voltage (Sambrook et al. 2001)

DNA or RNA bands can be visualized under UV transilluminator by using EtBr in the gel (Fig. 3).

### Pulsed-Field Gel Electrophoresis

Pulsed-field gel electrophoresis (PFGE) is a technique used for the separation of large deoxyribonucleic acid (DNA) molecules by applying to a gel matrix an electric field that periodically changes direction.

While in general small fragments can find their way through the gel matrix more easily than large DNA fragments, a threshold length exists above 30–50 kb where all large fragments will run at the same rate and appear in a gel as a single large diffuse band. However, with periodic changing of field direction, the various lengths of DNA react to the change at differing rates. That is, larger pieces of DNA will be slower to realign their charge when field direction is changed, while

smaller pieces will be quicker. Over the course of time with the consistent changing of directions, each band will begin to separate more and more even at very large lengths. Thus separation of very large DNA pieces using PFGE is made possible.

### Introduction

All living organisms maintain homeostasis, which necessitates that the concentration of ions within the body differs from the outside environment. As a result, a voltage develops across the skin. In an aquatic environment, this voltage has the potential to leak out and create a charge distribution around the body. These charges can be detected by specialized organs known as electroreceptors. Because electroreception relies upon a conductive medium in which to operate, it is restricted to aquatic species, or species that forage in moist environments.

### Prevalence

Electroreception is an ancient sensory modality that arose at the base of the vertebrate clade (Albert and Crampton 2005). It remains widespread among extant taxa but has been largely lost among the most speciose groups, the amniotes and actinopterygian (ray-finned) fishes. Among the agnathans, it is found in the Petromyzontiformes (lampreys) but is absent in the Myxiniiformes (hagfish). Among the

gnathostomes, it is present in the Chondrichthyes and most of the Osteichthyes, with the exception of the Holostei (gars and bowfin) and the Euteleostei. Despite its loss in the Euteleostei, it has re-evolved within the Ostariophysi (catfishes and knifefishes). In addition to its reappearance within some members of the euteleost lineage, electroreception has also independently re-evolved within two amniote lineages: the monotremes (platypus, echidna) and most recently in a single species of cetacean, the Guiana dolphin, *Sotalia guianensis*. Among the amphibians, electroreception is identified in the aquatic larval forms of caecilians and some urodeles (salamanders), but not the anurans (frogs). Although electroreception is taxonomically widespread, the total number of extant species that are electroreceptive is only about 10% of the total number of species within the vertebrate clade (Albert and Crampton 2005).

Despite the diversity of species that have been documented to be electroreceptive, the majority of research on electroreception is devoted to either the electrogenic mormyrid and gymnotid fishes or the largely non-electrogenic elasmobranch fishes (sharks and rays). Both groups utilize ampullary electroreceptors, which are tuned to low-frequency stimuli, to passively detect the bio-electric fields of prey. Ampullary electrosensory organs were first described in the sixteenth century from sharks and rays, and the elasmobranchs are renowned for their acute electrosense.

### Structure

Electroreception in elasmobranchs is mediated by a sensory system known as the ampullae of Lorenzini. The ampullae of Lorenzini consist of hundreds to thousands of glycoprotein-filled tubules which extend from pores on the surface of the head and body of elasmobranchs to blind-ending ampullae within the head that are lined with sensory hair cells. The glycoprotein gel is highly conductive with a conductivity almost equal to that of seawater (Murray and Potts 1961). In contrast, the cells that comprise the walls of the tubules are bound by tight junctions, which serve

to insulate the gel in the tubules from the surrounding tissues within the head (Waltman 1966). Compared to the walls of the tubules, shark tissue and the skin offer a relatively low electrical resistance, which means that the basal surface of the electrosensory cells in the head will be at nearly the same voltage as the surrounding seawater immediately adjacent to the head in that region. In the presence of an environmental electric gradient, the apical surface of the electrosensory cells facing the lumen of the ampulla will be at the same potential as the pore opening of the insulated tubule. The difference in electric potential from the pore opening on the surface of the head to the basal surface of the electrosensory cells lining the ampulla is a function of the position of the pore and length of the tubule with respect to the electrical voltage gradient across the head. This likely enables the animal to derive magnitude and direction information from environmental electric fields, which provides it with a richly detailed electric landscape.

## Function

The ecological function of the ampullae of Lorenzini remained uncertain for many years because electrophysiological experiments demonstrated that the system responded to a variety of stimuli, including mechanical pressure, temperature changes, salinity changes, and electrical stimuli. Behavioral experiments finally determined that the ampullae of Lorenzini act as electroreceptors, which can detect the presence of prey (Kalmijn 1971). Subsequently, electroreception was demonstrated to be used for mate detection (Tricas et al. 1995) and predator detection (Sisneros et al. 1998). It is also hypothesized that elasmobranchs can utilize their electroreceptors to detect the electric fields induced around their body as they swim through the earth's magnetic field (Kalmijn 1974). An extension of this hypothesis is that sharks might use their electroreceptors to enable them to orient to geomagnetic anomalies on the sea floor (Klimley 1993). Although there is a theoretical basis for support of these magnetic-induction-based hypotheses, definitive empirical data are lacking.

## Tuberous Electroreceptors

In addition to passive electroreception mediated through the ampullary electroreceptors, which respond best to low-frequency (<50 Hz) stimuli, electrogenic species, such as the gymnotids and mormyrids, also possess specialized tuberous electroreceptors, which are best tuned to higher-frequency stimuli of 50–2000 Hz (von der Emde 1998). The tuberous electroreceptors work in conjunction with the electric organ discharge (EOD) in these electrogenic species to detect the active EOD of other electrogenic individuals (electrocommunication). Sympatric species produce species-specific EODs, which facilitate identification of conspecifics for mating. The tuberous electroreceptors are also used to detect environmental distortions of their own self-generated electric fields (electrolocation). This enables these species to successfully navigate their environment by sensing and avoiding the presence of conductive and resistive objects. Thus, the tuberous electroreceptors can serve dual purposes, electrocommunication and electrolocation, and, when combined with ampullary electroreceptors for prey detection, can provide the animals with a comprehensive survey of their electrical environment.

Because humans lack an electric sense, we fail to appreciate the wealth of electrical information available in the environment. All living organisms in an aquatic medium generate an electric field around their body, which varies in the range from microvolts to millivolts, and these bioelectric fields provide an important sensory cue that can serve to inform electro-sensitive species. The persistence of electroreception throughout the vertebrate clade, and its reappearance in numerous lineages, illustrates the evolutionarily adaptive value of electroreception.

## Elektrokardiography (EKG)/ Electrocardiography (ECG)

Jacqueline Hill Tudor  
Ohio University, Lancaster, OH, USA

## Historical Perspectives

Elektrokardiography (EKG), or electrocardiography (ECG), is a technique that records the

electrical activity of the heart. The early work of Italian physician and physicist Dr. Luigi Galvani laid the foundation for the field of electrocardiography when he discovered and recorded electrical currents in frog leg skeletal muscles, thus demonstrating that muscle is an electrically excitable tissue. Galvani's seminal findings were published in *De viribus electricitatis in motu musculari commentaries* (Translation: *Commentary on the Effect of Electricity on Muscular Motion*) in 1791 (Galvani 1791). In 1842, Carlo Matteucci observed that electrical currents accompanied each heartbeat in frog experiments. The works of Galvani and Matteucci provided a foundation for study of the electrical and mechanical events of the cardiac cycle. In 1887, Augustus Desire' Waller recorded the first electrocardiogram using a Lippman capillary electrometer and electrodes placed on a human subject's torso (Besterman and Creese 1979). The resulting electrocardiogram was of little clinical value, as the tracings showed only two deflections. Yet, Waller's contributions to the field of electrocardiography were invaluable, as he was first to demonstrate that the heart's electrical activity could be recorded. It was Willem Einthoven, Dutch professor of physiology at the University of Leiden, who was credited with the "discovery of the mechanism of the electrocardiogram" and his achievement earned him a Nobel Prize for Physiology and Medicine in 1924, 2 years after Waller's death. Einthoven initially utilized the Lippman capillary electrometer but made a mathematical correction accounting for inertia. By doing so, Einthoven was able to record five deflections on the electrocardiogram, which he named PQRST, perhaps to follow Descartes tradition (though no one knows for certain). At the 1893 Dutch Medical Meeting, Einthoven coined the term "elektrokardiogram," yet he attributed it Waller as a token of respect (Snellen 2015). In contemporary scientific discourse, the term electrocardiogram (ECG) is also used to refer to the "elektrokardiogram" (EKG) named by Einthoven. It was also Einthoven who first speculated that there may be differences in the electrocardiograms of healthy and diseased hearts. This prompted Einthoven to improve the fidelity of electrocardiogram

recordings. In 1901, Einthoven developed a string galvanometer capable of producing high-quality electrical recordings (Einthoven 1903, 1964). Sir Thomas Lewis, a British cardiologist, was another prominent figure in the history of the early electrocardiogram. Lewis' notable accomplishment was using the ECG for the characterization of cardiac arrhythmias; he first identified atrial fibrillation and flutter on the ECG (Lewis 1921). Others also worked to use the ECG for clinical applications. In 1906, Willem Einthoven was the first scientist to observe heart block on the ECG (Cooper 1986). Frank Norman Wilson receives recognition for using the ECG to observe bundle branch block (Wilson et al. 1932).

### Brief Overview of Heart Anatomy

The heart is a valved, muscular structure responsible for pumping blood through the blood vessels of the body (Fig. 1a). The heart is a critical component of the nutrient and gas delivery system of the mammalian body. The mammalian heart contains four chambers. The two superior blood-receiving chambers are called atria, while the inferior blood-pumping chambers are termed ventricles. The two atria are separated by the interatrial septum, while the two ventricles are separated by the interventricular septum. The septa of the heart ensure that blood on the left and right sides of the heart are isolated from each other. The heart also contains two atrioventricular valves and two semilunar valves. The atrioventricular (AV) valves are located in between the atria and ventricles. The AV valves are able to open and close, thereby regulating blood flow between the atrium and ventricle. When the AV valves open, blood moves into the ventricles from the atria. When the AV valves close, the atria relax and fill with blood from the systemic circulation (right atrium) or pulmonary circulation (left atrium) while the ventricles contract and pump blood to the lungs (via right ventricle and pulmonary arteries) or systemic circulation (via left ventricle and aorta). The heart also contains valves called semilunar valves,

which are found between the ventricles and great vessels (pulmonary artery on right side; aorta on left side) of the heart. The semilunar valve between the right ventricle and pulmonary artery is called the pulmonary semilunar valve. The semilunar valve between the left ventricle and aorta is called the aortic semilunar valve (Saladin 2017).

### Path of Blood Flow Through Heart and Role of Pressure

The right side of the heart receives oxygen-poor blood from the systemic venous circulation (and coronary veins). The superior and inferior vena cavae drain oxygen-poor blood into the right atrium (Fig. 1b). As the volume of blood increases in the right atrium, the pressure climbs within the right atrium. When pressure in the right atrium exceeds the pressure in the right ventricle, the right AV valve opens and blood moves into the right ventricle. As blood moves into the right ventricle, the volume and pressure increase in the right ventricle. When the pressure in the right ventricle exceeds the pressure in the right atrium, the right AV valve closes and the right ventricle contracts. As the pressure in the right ventricle exceeds the pressure in the pulmonary artery, the pulmonary valve opens and blood moves into the pulmonary artery. The oxygen-poor blood is carried to the lungs by way of the left and right pulmonary arteries. After the blood undergoes gas exchange in the lungs, dropping off carbon dioxide and picking up oxygen, it returns to the left side of the heart via the left and right pulmonary veins (Fig. 1c). The pulmonary veins drain into the left atrium. As the left atrium fills with blood, the pressure inside the left atrium increases. When the pressure in the left atrium exceeds the pressure in the left ventricle, the left AV valve opens and blood moves into the left ventricle. As blood collects in the left ventricle, the pressure increases. The left AV valve closes and the left ventricle contracts. As the pressure in the left ventricle exceeds the pressure in the aorta, the aortic valve opens and blood moves into the aorta. Blood traveling through

atrium. RV = Right ventricle. (c) Path of blood flow through left side of heart. Arrows indicate movement of oxygen-rich blood through left side of heart. LA = Left atrium. LV = Left ventricle. Right pulmonary veins are not shown

the aorta continues through the systemic arterial circulation, thereby delivering nutrients and gases while picking up waste materials, in the cells and tissues of the body. It is important to note that the events occurring on the right and left sides of the heart are occurring nearly simultaneously. The ventricles contract as a unit, while the atria relax. The atria contract as a unit, while the ventricles relax. The timing of contraction/relaxation events is coordinated by an electrical

system of the heart called the cardiac conduction system (Fox 2016; Saladin 2017).

## The Electrical Activity of the Heart

The cardiac cycle consists of contraction and relaxation events, named systole and diastole, respectively. In each instance of systole, the

contraction event is preceded by an electrical signal. Thus, the electrical events occurring in the heart serve as precursors for the mechanical aspects of cardiac function (i.e., pumping blood); a deviation in normal electrical function in the heart can translate to a mechanical deviation from normal. The structures which generate the rhythm of the heart are part of the cardiac conduction system. The cardiac conduction system is comprised of electrically excitable pacemaker cells and nerve fibers which extend throughout the myocardium (muscle) of the heart. The pacemaker of the cardiac conduction system may be neurogenic (made of neurons) or myogenic (made of modified muscle cells). Invertebrates, such as decapod crustaceans (shrimps, crabs, etc.), utilize a neurogenic pacemaker (Wilkins 1999). Vertebrates, including primates, utilize a myogenic pacemaker. In vertebrates, the cardiac conduction system is comprised of a sinoatrial (SA) node, atrioventricular (AV) node, atrioventricular (AV) bundle, left and right bundle branches, and Purkinje fibers (Fig. 2). The sinoatrial node, the atrioventricular node, and Purkinje fibers all have the capacity to serve as the pacemakers of the cardiac conduction system, but the pacemaker that fires action potentials with the highest frequency will set the heart rate by overriding the

electrical activity of the slower pacemakers (Boron and Boulpaep 2012; Saladin 2017).

### Sinoatrial (SA) Node

The SA node is the fastest pacemaker in the heart and fires at a rate of approximately 60–100 action potentials per minute, compared to the AV node's 40 action potentials and the Purkinje fibers' 20 action potentials per minute. Because it is the fastest pacemaker, the SA node acts as the primary generator of cardiac rhythm in a healthy mammalian heart. The SA node is located in the right atrium near the superior vena cava. The SA node is comprised of pacemaker cells which are automatic, meaning the cells fire action potentials spontaneously and at regular intervals without need for nervous system stimulation. Unlike neurons and skeletal muscle cells, SA node cells do not have a stable resting membrane potential; rather the pacemaker cells undergo a steady depolarization from  $-60$  mV towards threshold. This depolarization is called the pacemaker potential. The cells of the SA node have a low threshold for action potential firing, approximately  $-40$  mV. Once threshold is reached, voltage-gated calcium open, allowing rapid influx of calcium producing

**Elektrokardiography (EKG)/Electrocardiography (ECG), Fig. 2** Path of electrical excitation in cardiac conduction system. The action potential propagation pattern of

the cardiac conduction is shown, starting with the sinoatrial node and terminating at the Purkinje fibers

a fast depolarization (Fig. 3). Following depolarization, voltage-gated potassium channels activate and a steady outward potassium current causes the cell to repolarize. The SA node pacemaker action potential duration (APD) is approximately 0.8 s. Although the SA node generates cardiac rhythm independent of nervous system function, it is innervated and regulated by both divisions of the autonomic nervous system (ANS). Under “rest and digest,” the parasympathetic division of the ANS releases acetylcholine onto the SA node, lowering the rate of action potential firing. The vagus nerve, a major parasympathetic nerve, continuously releases acetylcholine onto the pacemaker cells (called vagal tone), thus driving down the intrinsic firing of the SA node to 70–80 action potentials per minute. Acetylcholine, by decreasing the action potential firing rate in the SA node, lowers heart rate. The sympathetic division of the autonomic nervous system, by way of postganglionic sympathetic neurons, releases norepinephrine onto the SA/AV node cells. Norepinephrine, as well as epinephrine from the adrenal medulla, decreases action potential duration and increases the action potential firing rate of SA/AV node cells. It is

predominantly the effect of norepinephrine that drives the increases in heart rate observed under the sympatho-adrenal (“fight-or-flight”) stress response (Boron and Boulpaep 2012). When the SA node generates an action potential, the electrical excitation spreads throughout the atrial myocardium and stimulates the AV node.

### Atrioventricular (AV) Node

The signal from the SA node electrically stimulates the second part of the cardiac conduction system, the atrioventricular (AV) node. The atrioventricular node is located superior to the right atrioventricular valve and it shares many physiological traits with the SA node. In the event that the SA node is damaged, the AV node will generate the heart rhythm at a rate of approximately 40 beats per minute. The AV node also has the same conduction velocity as the SA node (0.05 m/s). Additionally, the action potential waveform of AV node pacemaker cells is very similar to that of the SA node cells. The AV node is important in that it serves as the electrical gateway between the atria and the ventricles,

and all signals traveling through the atria must pass through the AV node to reach the ventricles. Due to the presence of a fibrous skeleton between the atria and ventricles, the AV node serves as the only electrical access point between the atria and ventricles. Like the SA node, the AV node is innervated by the parasympathetic and sympathetic nervous systems, and it exhibits similar physiological responses to acetylcholine, norepinephrine, and epinephrine (Boron and Boulpaep 2012; Hall 2016).

### His-Purkinje Network and Ventricular Muscle

The atrioventricular bundle, bundle branches, and Purkinje fibers are part of the His-Purkinje system that begins after the AV node. The atrioventricular bundle (Bundle of His) is located at the inferior interatrial septum near the right atrioventricular valve. The electrical signal moves slowly through the AV bundle, allowing time for ventricular filling. The AV bundle branches into left and right bundle branches. The left bundle branch

supplies the left ventricle with innervation, while the right bundle branch supplies the right ventricle with innervation. The left and right bundle branches enter the interventricular septum and terminate at the apex. The electrical signal is carried into the ventricular myocardium by the Purkinje fibers. The Purkinje fiber cells have the slowest intrinsic pacemaker firing rate (only 20 beats per minute) and in a healthy heart, do not set the cardiac rhythm (Saladin 2017). In a healthy individual, the Purkinje network acts a conduction relay to rapidly conduct signals to the ventricular myocardium. The cells of the Purkinje network have a conduction rate of 4 m/s, 80 times faster than the SA/AV nodes. However, the Purkinje fibers can serve as a pacemaker for the heart in the event that the SA and AV nodes are nonfunctional (Boron and Boulpaep 2012). The Purkinje fibers directly innervate the ventricular myocardium, and they stimulate the ventricular muscle cells to generate an action potential (Fig. 4). Ventricular myocytes have a resting membrane potential of  $-80$  mV. When the electrical signal from the cardiac conduction system stimulates the myocytes, voltage-gated

**Elektrokardiography (EKG)/Electrocardiography (ECG), Fig. 4** Ventricular muscle action potential. The phases and ionic movements of the ventricular myocyte action potential are shown in this figure

sodium channels open, activating a fast inward sodium current responsible for the depolarization phase of the action potential. At depolarized values near the peak of the action potential, voltage-gated sodium channels inactivate while voltage-gated calcium channels activate and open. Calcium influx through these channels produces the plateau phase of the myocyte action potential. Importantly, the calcium entering during the plateau phase will be utilized to liberate calcium from intracellular stores (in sarcoplasmic reticulum of myocyte) to use for contraction. At the end of plateau, voltage-gated calcium channels inactivate while voltage-gated potassium channels activate and open. The resulting outward potassium current drives repolarization. The ventricular myocyte action potential duration (APD) is approximately 250 ms. Ventricular muscle cells are functionally connected by gap junction channels. Thus, when a ventricular muscle cell is stimulated via Purkinje fiber, the wave of electrical excitation will pass through functionally connected cells in a given chamber of the heart. Additionally, the ventricular myocardium is innervated by the sympathetic, but not the parasympathetic nervous system. The effect of epinephrine and norepinephrine on ventricular muscle is to increase intracellular calcium and therefore force of muscle contraction (Widmaier et al. 2016).

## The Electrocardiogram

In 1901, Einthoven found that when electrodes are placed on a human or animal subject, a tracing can be produced of action potentials spreading between the negatively and positively charged electrodes. He utilized an additional electrode to ground the current. The tracings varied according to the location of the electrodes, and Einthoven subsequently described three angles or leads which formed a triangle with the heart in the middle. Today, this is known as Einthoven's Triangle; the three electrodes are known as the limb leads I, II, and III (Fig. 5a) (Becker 2006). There are also six leads called precordial leads (V1–V6) placed on the chest wall (Noble et al.

1990). The patient is instructed to relax with hands in the supine (facing anteriorly) position. Simultaneous recordings are made from the electrodes, and the resulting ECG is a composite of all the electrical activity of the heart (VanPutte et al. 2014). It does not represent a single action potential, but it is rather a representation of all action potentials occurring during the cardiac cycle. Figure 5a shows a typical electrocardiogram of an individual in sinus (normal) rhythm. The P wave is produced when an electrical signal from the sinoatrial (SA) node is generated by the pacemaker cells, depolarizing the left and right atria. The P wave is produced during the depolarization phase of the pacemaker action potential. Atrial contraction occurs approximately 100 ms after the P wave during the PQ segment. The electrical signal, as it travels through the AV bundle, bundle branches, and Purkinje fibers, does not produce any discrete waves on the ECG. The QRS complex is the result of ventricular myocyte depolarization. The QRS complex is large because the ventricles of the heart have the most muscle mass and generate the greatest amount of current. Atrial repolarization and relaxation also occur during the QRS complex, but the electrical event is obscured by the QRS complex. The T wave represents ventricular repolarization, which immediately precedes diastole. The T wave is produced by the repolarization noted on the myocyte action potential waveform. The repolarization process takes longer than depolarization, which accounts for the wider T wave (as compared to the QRS complex). In rare instances, the U wave is noted on the ECG. The U wave follows the T wave and represents repolarization of papillary muscle which attach to AV valves within the ventricle (Boron and Boulpaep 2012). There are also several intervals and segments that are physiologically relevant (Fig. 5b). The PQ segment indicates how long it takes the signal to propagate from the SA to AV node. The PR interval is a measurement of the how long it takes for the signal to propagate through the AV node to the ventricles. The QRS interval allows one to measure how long it takes the electrical signal to spread throughout the ventricles. The QRS complex represents ventricular

**Elektrokardiography (EKG)/Electrocardiography (ECG), Fig. 5** The electrocardiogram. (a) This figure shows Einthoven's Triangle and the relationship between electrical vectors (left) used to create a typical

electrocardiogram (right). Roman numerals I, II, and III denote the limb leads I, II, and III, respectively. RA = Right arm. LA = Left arm. LL = Left leg. (b) Intervals and segments are shown on the ECG

myocyte depolarization (see Fig. 4). Additionally, atrial repolarization and relaxation occur during the QRS interval. Ventricular contraction begins

immediately after the QRS complex. The plateau phase on the ventricular myocyte action potential waveform is represented by the ST segment,

Cardiac conduction system and the ECG. This figure shows the relationship between the events occurring in the cardiac conduction system and the ECG. This figure also notes atrial and ventricular systole events

E

which also signifies ventricular contraction. The QT interval represents how long the ventricular remain in a depolarized state. This interval gets shorter as heart rate increases. The RR interval is the time between ventricular depolarization events and is used to measure heart rate. The cardiac conduction system, discussed above, is responsible for producing the waves, intervals, and segments of the ECG. A summary of the path of electrical excitation of the cardiac conduction system and its relations to the waves, intervals, and segments of the ECG is reflected in Fig. 6. Systole events are also noted in Fig. 6. In addition to evaluating waves, intervals, and segments, the ECG is also used to determine the electrical axis of the heart (Goldberger et al. 2018). All of the action potentials, including the magnitude and direction of each, occurring in the heart are represented by vectors. The vectors for individual myocytes can be summed to create a mean electrical axis for the heart. Deviation from the normal electrical axis occurs during pathological states such as cardiac hypertrophy

(enlarged heart) (Kashou and Kashou 2018) or myocardial infarction.

## Diagnostic Value of the ECG

The ECG is a powerful tool used in the diagnosis of pathological conditions. Heart pathologies such as myocardial infarction, arrhythmias, conduction block, and heart enlargement may be reflected on the ECG. However, pathological states of other organ systems can cause deviations in the ECG. For instance, hormone and electrolyte imbalances can have cardiovascular consequences which are reflected on an ECG. Any deviation in the normal sinus rhythm of the heart is called an arrhythmia. Most arrhythmias are discernable on the ECG; thus the ECG serves as an invaluable diagnostic tool for clinicians. Some arrhythmias are more serious than others. For instance, ventricular fibrillation refers to a condition in which the ventricles do not contract in a coordinated, unified manner. The ventricular muscle cells

depolarize quickly and irregularly. As a result of ventricular fibrillation, the heart is unable to pump blood, because it cannot generate a unified, productive contraction. Ventricular fibrillation also means that there is no coronary blood flow, and the myocardium dies of ischemia (lack of blood flow). The ECG of a fibrillating heart shows small, erratic waves with no discernable pattern. Ventricular fibrillation can be fatal if not reversed. Defibrillation is a life-saving procedure that aims to shock the conduction system back into a sinus rhythm (Hall 2016). Atrial fibrillation occurs when the atria depolarize approximately 300–600 times per minute, yet the action potentials are of such low magnitude that discrete P waves are not discernable. The signals generated in the atria will reach the AV node; however, the AV node will limit the impulses traveling to the ventricles and will attenuate the signal rate. The ventricles will be stimulated 100–200 times per minute under atrial fibrillation. The ECG will also show elevated but erratic heart rate. Other cardiac arrhythmias involve the use of a non-SA node pacemaker to set the heart rhythm. For instance, if the SA node is damaged, the ECG may show an absent P wave indicating a nodal rhythm. A nodal rhythm occurs when the AV node assumes the role of setting heart rhythm. An individual experiencing a nodal rhythm will also have a heart rate of approximately 40–50 bpm. If the AV node is damaged, electrical signals from the SA and AV nodes will not reach the ventricles. In this state, the ventricular myocardium is solely responsible for generating the cardiac rhythm. A cardiac rhythm generated by the ventricular myocardium is called an intrinsic ventricular (idioventricular) rhythm. An individual experiencing intrinsic ventricular rhythm will have a resting heart rate of 20–40 bpm. Arrhythmias may also be categorized as partial or complete conduction block disorders. Partial conduction block disorders include first-degree AV block, second-degree AV block, intermittent block, and bundle branch block. First-degree AV block is characterized by a long PR interval. Physiologically, a first-degree AV block refers to a slower than normal conduction of impulses through the AV node. Intermittent block is a partial conduction disorder in which only some

electrical signals are conducted. Second-degree AV block has two subtypes, Mobitz type I block and Mobitz type II block. Mobitz type I block is characterized by the PR interval that gets progressively longer until the AV node fails and the ventricles skip depolarization cycles. In Mobitz type II blocks, the PR interval does not change, but an occasional QRS complex/T wave is missing nonetheless. The ECG will show a P wave but remain flat until the next P wave. Bundle branch blocks are typically characterized by failure of the Bundle of His or Purkinje fiber system. Both left and right bundle branch blocks are discernable on the ECG by a wide QRS interval. The ST segment is of great clinical importance, as an elevation in the ST segment can be indicative of a myocardial infarction. Cells near the sight of ischemia experience anoxic injury and remain in a depolarized state. Additionally, coronary artery spasms during a MI can trigger a ST segment elevation. Additionally, the ECG will often appear abnormal in instances of electrolyte imbalance. Potassium imbalances (see “Homeostasis” entry for normal potassium levels) can prove deadly if not reversed. Potassium efflux drives repolarization and relaxation of excitable muscle tissue. If extracellular (plasma) levels of potassium are elevated, excitable tissues will struggle to repolarize. If plasma levels of potassium are elevated (hyperkalemia), changes in the ECG will occur if the plasma potassium levels continue to rise. Initially, a person may exhibit a prolonged PR interval and tented T wave at slight deviations (6 mM). As hyperkalemia progresses, the QRS complex can become prolonged, obscuring the P wave (8 mM). At dangerously high levels of plasma potassium (10 mM), ventricular fibrillation can occur (Boron and Boulpaep 2012). Hyperkalemia rarely occurs in healthy individuals. Hypokalemia, or low levels of plasma potassium, is reflected by a flat T wave and large U wave on the ECG. Potassium can be lost via sweating mechanisms on hot days where dehydration is a concern. Additionally, some individuals may have low dietary intake of potassium, causing hypokalemia. The electrocardiogram has greatly enhanced the clinician’s ability to diagnose cardiac disorders using this safe, noninvasive technique.

## Introduction

Elephants are the largest land-dwelling mammals alive today. They are long-lived (living into their 60s or 70s) and highly social animals with slow life histories. Their lives have frequently overlapped with human societies, and thus their ecology has been affected greatly by habitat

fragmentation, legal and illegal hunting, and human-elephant conflict. Thus, investigations of behavior are at times subject to the confounding effects caused by human interference. Additionally, collecting long-term data on the life history of elephants can be challenging and, at times, fragmented due to their slow physical development and long life spans.

There are two well-established species of elephants alive today of the order Proboscidea – *Loxodonta africana* and *Elephas maximus*. More commonly, these elephants are referred to as the African and Asian elephant. The African elephants can be divided into two subspecies (or species, depending on the source (Blanc 2008; Hart et al. 2008)), *Loxodonta africana cyclotis* (African forest elephant) and *Loxodonta africana africana* (African bush elephant). There is debate in the scientific community with regard to the African savannah and forest elephant and whether these two populations should be considered distinct species within the genus *Loxodonta*.

African savannah elephants are found in eastern, southern, and western Africa, while forest elephants are found in the central and western regions of the continent (Sukumar 2003). African elephants have been classified as “vulnerable” by the International Union for Conservation of Nature (IUCN) with a rising population (Blanc 2008). An enormous amount of research on African savannah elephants has arisen from Amboseli National Park, specifically produced by Dr. Cynthia Moss. Moss’ study of African elephants is the longest continuous, official study of any elephant species. The data collected at Amboseli, however, cannot speak across all ecological conditions in which *Loxodonta africanus* live. Though the Amboseli population has been comparatively undisturbed by human activity over the course of the data collection, these elephants were by no means isolated from human interaction; the primary cause of death in adult elephants in this study population is related to human activity (Moss 2001). Further, the span of the presented research does not contain the full life span of a single elephant. All this being said, the data collected at Amboseli certainly gives a better understanding to the life history of both

African and Asian elephants, providing richer information than a captive population could replicate (Moss 2001).

Asian elephants live primarily in India (around 60% of wild Asian elephants) but also in a variety of other countries in Southeast Asia – primarily Myanmar, Indonesia, Sri Lanka, Thailand, and Malaysia (Sukumar 2006). This slightly smaller species is currently thought to be divisible into three subspecies – *Elephas maximus indicus* (living primarily in India), *maximus* (Sri Lanka), and *sumatranus* (Indonesia) (Choudhury et al. 2008). Unlike the African elephant, Asian elephants are listed as “endangered” by the IUCN and have been since 1986 (Choudhury et al. 2008). It is estimated that the Asian elephant has been eliminated from as much as 95% of its original range (Sukumar 2006). Much of the data regarding Asian elephants has been synthesized by Dr. Raman Sukumar, an ecologist working in the Center for Ecological Sciences at the Indian Institute of Sciences.

African and Asian elephants, though similar in a variety of their life history traits, are distinct both behaviorally and physiologically. Additionally, they face very different challenges with regard to their conservation. The different statuses across the three species have led to discrepancies in their study, especially given the numerous challenges of studying elephants even in the best of circumstances.

## Reproduction

Female elephants begin estrous upon reaching sexual maturity. Each species varies in the exact number of days and manner of signaling while in estrous. Estimates of the estrous cycle in a population of Asian elephants in Sri Lanka found Asian elephants go into their estrous cycle for 18–27 days and begin at sexual maturity between the ages of 11 and 14 – though this varies significantly per population (Sukumar 2003). Their gestation period is extremely long as well, lasting between 20 and 22 months. When in estrous, females will signal their state to surrounding males. This signaling has been recorded in

both African and Asian elephants. Specifically, a number of auditory and chemical signals in addition to behavioral indicators of estrous have been noted in African savannah elephants living in Amboseli (Sukumar 2003).

Behaviorally, female elephants go through the following four stages during estrous: (1) a wariness period during which females are hesitant in nearing bulls and are intolerant of their approaching, (2) the estrous walk during which the female will walk with her head held up in reaction to an approaching male, (3) a chase period during which she will run away from or in an arc around approaching bulls, and (4) the courtship period. Here, physical proximity is decreased and the female closes in on a chosen bull while the bull turns away other competing males. This period can last multiple hours while the actual mating is comparatively short. The couple may then mate multiple times over the course of the day or more (Sukumar 2003).

It is not just females that signal their readiness to mate. Males go through periods known as *musth* during which their sexual interest peaks, as does their aggression. Musth is defined by the enlargement and secretion of the temporal gland, increased aggression and sexual activity, and dribbling of urine (Vidya and Sukumar 2005). This period can last days or months. The musth phenomenon was discovered originally in observations of Asian elephants, though it has been found to occur in African elephants as well (Sukumar 2003). Relatively recently Poole and Moss (1981) described the same process with a few small differences between species. Similar to the female estrous signaling, they have detailed the behavioral components of musth for the Amboseli population; while the general outline of these behaviors applies to both the Asian and African elephant, there are a few noted differences (Sukumar 2003). To begin, the male begins with a musth walk where he walks with his head high, chin tucked, and ears spread. He also will swing his head and tusks. He then moves into a tusking phase where he goes to his knees and tusks at the ground. As he does so, he will throw lumps of mud and grass while discharging fluid. This tusking behavior, however, has not been seen

universally across populations (Sukumar 2003). The male will also scent mark more frequently, rubbing his temporal glands against trees (Poole and Moss 1981). Additionally, there is an auditory communicatory signal of musth named the “musth rumble.” This sound is of very low frequency and garners a specific auditory response from females. Lastly, the male will urinate with a sheathed penis at a very slow rate for an hour or more. He may also urinate with his penis retracted in order to spray urine on his back legs (Poole and Moss 1981). Aside from the tusking behavior, these behaviors have been noted – at least anecdotally – across species. In African elephants, however, musth may also be accompanied by an “ear wave” during which the male will move (wave) one ear at a time (Sukumar 2003; Poole and Moss 1981).

Though musth is always a postpubertal phenomenon, the age of first musth is variable across populations and species. In Asian elephants, musth will begin from about 15 years of age. In the Amboseli population of African savannah elephants, however, elephants are at least 24 years of age upon first musth, and the average age is closer to 29 years of age. Further, regular onset of musth will not begin until the age of 35 (on average) (Lee and Moss 2002; Moss 2001; Sukumar 2003).

## Life Span and Mortality

In the Amboseli population, median age of first birth is 14.11 and the mean 13.67. The youngest known first birth in the population was recorded at 8.9 years and the oldest 21.6 years. On average, however, most elephants will have their first birth between 11 and 13 years. Additionally, though there are calves born year-round, the majority of calves (81%) are born between the months of November and May with an average interbirth period of one calf every 4.5 years. These elephants can reproduce well into old age, though their fecundity declines after around 50 years of age (Moss 2001).

Mortality in adults was still primarily caused by human activity throughout the

30 years of observation. In juveniles, however, 80% of mortality occurred from natural causes. It should be noted, however, that only 231 of the 691 deaths had causes that could be determined with certainty. Furthermore, though the sex ratio at birth between males and females was not far from 1:1, juvenile mortality is significantly different between the sexes (Moss 2001). In the Amboseli population, males had a 75% chance of living to age 10, whereas for females it was an 85% chance. More strikingly, because on average males don't enter musth regularly until the age of around 30, their chances of surviving to this point of reproductive maturity were only 39%. Whereas females, who on average reach reproductive maturity at age 14, have a much higher percent chance of living until they are reproductively mature – 82%. Overall (perhaps in part due to the age of reproductive maturity), females have a 70% chance of living to produce at least one offspring, whereas males only have a 50% chance of living to regularly enter musth (Moss 2001).

Estimating the life span of truly wild Asian elephants has been a greater challenge. Much research dealing with the life span of Asian elephants has been done using semi-captive populations who face different environmental obstacles regarding longevity. These semi-captive elephants are allowed to “intermingle” with wild elephants and forage independently. They are also used, however, as workers in the Myanmar timber industry. These individuals make up the largest captive population of Asian elephants. A portion of the elephants here are captive born, and the others are wild-caught (though this is now forbidden). Of the wild-caught elephants, the longest lived is 83 years. Further, the earliest age of first birth was 5.28 years with an average interbirth interval of 5 years (Robinson et al. 2012). Previously, Sukumar reported the average age of first birth to be closer to 17–18 years in Asian elephants living in Biligirirangans, whereas the Myanmar semi-captive elephants had an average first birth between 18 and 23 years of age (Sukumar 2003). Lastly, studies have found

that probabilities of survival remain relatively constant up to age 25 after which they decrease (Robinson et al. 2012).

## Social Structure and Cognition

Elephants have prolonged development periods and exhibit a great deal of social learning. All species of elephant produce precocious offspring that rely on their smell, touch, and sound to find mothers for suckling. The calves will remain dependent on the mother's milk until their 3rd month. In the 4th month, however, they are generally able to use their trunk for foraging on a variety of greenery though they continue to nurse at least into their 9th month. Though at the age of 1 year, the calves are nutritionally independent and take part in grooming, there remain behavioral and social skills that are undeveloped. To continue developing these skills, calves spend a great deal of time with their mothers, in addition to spending time playing with other calves (Sukumar 2003).

In African elephants, males grow faster and continue growing for more time than do their female counterparts. Further, unlike the females, males will disperse from their mother between 9 and 18 years of age (Vidya and Sukumar 2005). Though bulls do disperse, they are not completely solitary – Moss and Lee have calculated that Amboseli bulls spend less than one-third of their time alone (Lee and Moss 2002; Moss 2001). They are accompanied often by other males or in the presence of female groups. In Asian elephants, males will also disperse around the age of sexual maturity, though the age range is closer to 10–15 years of age. Further, it has not been clearly determined whether this dispersal is locational or social (Vidya and Sukumar 2005).

Female African elephants do not disperse and instead stay in matriarchal groups. The female social structure is far more dynamic than that of the males. They form highly complex social networks among different family

groups known as “bond” or “kinship” groups (Vidya and Sukumar 2005). Over 80% of their time is spent in the family group, and their behaviors are highly coordinated. The structure of these groupings varies across species and subspecies of elephant. In contrast, groups of African forest elephants consist of single adult females and their dependent offspring – they have not been found to form the same kinship/bond groups as African savannah elephants. Asian elephants, however, have been seen to form family groups similar to those of the African savannah elephants; however there is no long-term study confirming this observation. A recent analysis on Asian elephant haplotype, however, has shown maternal relatedness within the groups, suggesting a similar group structure to the African elephant (Vidya and Sukumar 2005).

Furthermore, elephants are extremely intelligent beings. Though not advanced toolmakers like the great apes, relatively recent research has elucidated various manifestations of their intelligence in the form of long-term social and spatial memory. Though some of this data is anecdotal, it is supported by multiple experts in the field who have documented occurrences of such behaviors repeatedly. In one case, it was found that during a drought, only elephant groups with older matriarchs knew to leave their normal grounds to find a different watering hole. Additionally, in a playback study, it was found that elephants could recognize up to 100 different individual elephant calls from up to 1.5 km away (Hart et al. 2008). Lastly, whether elephants possess a “theory of mind” – meaning the animal is self-aware and can act based on the well-being of another – has been brought up for questioning. Evidence in favor cites elephants attuned focus on elephant bones, mirror recognition, and response to distressed group members. Their highly sophisticated social and emotional processing skills have been the subject of much scientific and public conversation, often in the context of elephant welfare in captivity (Hart et al. 2008).

### Synonyms

*Mirounga angustirostris*; *Mirounga leonina*;  
*Miroungini Mirounga*

### Introduction

Elephant seals, known colloquially as sea elephants, are part of a group of marine mammals called Pinnipeds, which means “fin-footed” (Wyss 1989). Pinnipeds are found globally and can be divided into three sections: true seals, eared seals, and walruses. Elephant seals fall under the true seal category and contain two sub-categories: southern and northern. The two elephant seal species were discovered to be taxonomically different species in 1866 (Stewart et al. 1994). The southern elephant seal’s Latin name, *Mirounga leonina*, means lion and may be a reference to the loud roaring vocalizations they emit when they want to warn off breeding competition. For the northern species, the Latin name, *Mirounga angustirostris*, means “narrow snout” and refers to the namesake, characteristic nose of adult males. Those of northern elephant seals are discernably thinner than

those of their southern cousins. They are sexually dimorphic, meaning males and females are physically distinguishable as adults.

While the northern elephant seals are the largest pinniped species in the Northern Hemisphere, the southern elephant seals are the largest in the world. All individuals have the same light to dark brown coloration and molt once a year. The males are easily differentiated from females, as they can grow up to five times larger and have the characteristic elongated snout that founded their common name (Folkens and Reeves 2008). Females can gestate and have one pup per year. Physical adaptations enable these animals to dive to extreme depths for up to 30 min, withstanding great pressure and freezing temperatures (Folkens and Reeves 2008).

### Description

Seals are built to exist on land but are most well-equipped for life in the water. True seals and fur seals look generally alike to the untrained eye but have some small key differences. Elephant seals have rounded, sleek bodies, sizable heads, small tails, and four flippers. Typically females will sexually mature by 3 years of age in the northern species, while the other species and sexes will take between 4 and 6 years (Geraci and Lounsbury 2005). Males grow their eye-catching, long snouts called a proboscis when they reach puberty. Their large, round bodies are kept warm by a layer of blubber just under their skin and coat of fur. They have large heads respective to their bodies and broad, thick shoulders and chests. This feature is more exaggerated in males than females, but both sexes have tapered torsos that end in long hind flippers. These hind flippers propel them in the water, moving laterally side to side and expanding in a fan shape to utilize more surface area (Folkens and Reeves 2008). Front flippers are used for steering underwater. Like other true seals, elephant seals do not have a rotating hip bone, which means they are unable to walk on all four limbs while on land. Instead, their terrestrial locomotion is scooting on their bellies, in an inchworm-type fashion (Geraci and Lounsbury

2005). Their fore-flippers may be used for occasional boosts but are otherwise not utilized on land. Elephant seals do have claws, and unlike fur seals, they have front flipper digits that are not entirely covered with skin and are separated by webbing (Folkens and Reeves 2008).

Northern elephant seals express more sexual dimorphism than their Antarctic cousins. Southern seals are sexually distinguished by their physical appearance, but the northern species' sexes differ in foraging behavior and molting season. Southern seals, being the largest, grow to be 5 m in length, while the northern species grows to just over 4 m (Geraci and Lounsbury 2005). Males can weigh up to 5000 and 2000 kg, respectively, with females weighing up to 900 and 600 kg (Folkens and Reeves 2008). Both species of elephant seals are tan to dark brown in color. Other than their greater size and characteristic noses, males can be identified by their robust, thick necks. They become thicker and calloused with size and age, collecting pink scars and mottling from years of fighting and molting (Folkens and Reeves 2008; Geraci and Lounsbury 2005). Females are generally between three to four times smaller than their male counterparts and do not have lengthy noses (Folkens and Reeves 2008). Females and pups are similar in appearance. After pups lose their silver or gray newborn fur, they too become dark brown dorsally with some lighter tan coloration on their ventral belly side (Folkens and Reeves 2008).

Northern seals' mouths hold eight pairs of teeth in the lower and upper jaws. Southern seals only have seven pairs in the bottom jaw. The largest and most intimidating of the teeth are the canines, growing to be 20 cm in the northern and 15 cm in the southern species (Folkens and Reeves 2008). Teeth located further in the mouth, behind the canines, are all the same peg shape and known as "post-canines" (Folkens and Reeves 2008; Geraci and Lounsbury 2005).

Elephant seals are the deepest divers in the pinniped family, and their foraging takes place where they cannot rely on much light (Le Boeuf and Laws 1994). The large size of their eyes hints that they rely heavily on eyesight to detect prey. True to form, their eyes are capable of adjusting to dark surroundings faster than other pinnipeds and

can perceive bioluminescence in the dim, unlit reaches of the subarctic oceanic hunting grounds (Folkens and Reeves 2008; Levenson and Schusterman 1999).

As true seals, sea elephants have no external, visible ear flaps. Their hearing thresholds above and under water are comparable to other true seals, with the exception of low frequencies under water, which suggests their hearing is actually very well adapted, particularly for hearing under water and at high pressures (Kastak and Schusterman 1999; Macdonald 2009). This marine adaptation comes at the expense of aerial hearing, though, as their auditory sense out of water is not sharp by comparison (Kastak and Schusterman 1999).

## Habitat and Locations

Northern elephant seals are only found in the Northern Hemisphere of the Pacific Ocean. Much of their distribution is unknown prior to the time of widespread hunting that diminished their prior population size (Stewart et al. 1994). Colonies are located in southern and central coastal California, as far north as Point Reyes and as far south as Isla Natividad in Mexico (Stewart et al. 1994). The largest colony is on the Channel Islands.

Southern elephant seals, as the name suggests, are only found in the Southern Hemisphere, but unlike their northern counterparts, their range is circumpolar. They span the southern Atlantic, Indian, and Pacific Oceans. Large breeding colonies have been established respectively on South Georgia, the Kerguelen Islands, and Macquarie Island (Boyd et al. 1996). Other than the coasts of Antarctica, exploratory and migrant seals have been seen in the most southern reaches of Australia, South America, and South Africa.

When southern elephant seals haul out, they prefer beaches of gravel or sand (Folkens and Reeves 2008; Le Boeuf and Briggs 1977). Southern elephant seals can dive up to 1500 m but generally stay at depths between 180 and 600 m (Folkens and Reeves 2008). Migration for foraging purposes will occur throughout the year,

outside of breeding season, and spans from the Antarctic coast to northern edges of the Southern Ocean. Outlying individuals have been reported as far north as Western Asia (Folkens and Reeves 2008).

Adults of both species are solitary; the only time they see conspecifics is during mating or molting (Folkens and Reeves 2008).

When they are not hauled out for molting or mating season, northern seals will range a grand span of the northeastern part of the Pacific Ocean. Unlike southern seals, northern seal migrations are sexually dimorphic and will differ in locale based on the sex of the animal. In the past, northern seals have been sighted as far west as Japan (Folkens and Reeves 2008). Average foraging dives of northern elephant seals are down to depths between 330 and 800 m and also last half an hour (Folkens and Reeves 2008). However, individuals have been noted to dive for up to 2 whole hours. They forage and avoid land for 8–10 months between the combined molting and breeding period.

## Diet

Population and individual diets will vary based on preferences and availability due to geographic location. All seals are carnivorous and have been known to eat birds and other seal species (Le Boeuf as cited in Riedman 1990). Their diet mainly consists of free-swimming fish, octopus, and squid, the size and species of which correlate to the age and size of the seal (Folkens and Reeves 2008; Clarke and Macleod 1982; Field et al. 2007). As suggested by their propensity to also spend time at sea floor depths, elephant seals may also forage for benthic creatures, notably elasmobranchs and amphipods (Folkens and Reeves 2008; Field et al. 2007). They hunt for prey that exhibits bioluminescence, which are more easily detectable in depths where little to no sunlight is able to penetrate (Folkens and Reeves 2008).

Southern elephant seals find most of their prey at depths between 180 and 600 m. They generally go after pelagic, or free swimming, fish and squid that reside there. Individuals have been tracked

diving repeatedly to benthic depths in subantarctic waters, suggesting that some seals will forage on the ocean floor for food as well (Folkens and Reeves 2008).

## Threats and Predators

Elephant seals will live to be in their mid to late teens (Folkens and Reeves 2008). The most accurate age estimation is accomplished by counting the layers of tooth growth that are the results of annual dentine deposits (Hohn 2009). Natural limiting factors of seal populations are comprised of natural predators (e.g., sharks, bears, cougars, and wolves), intense storms or weather, variability in food availability, and causes of disease like lungworm parasites and bacteria (Brownell et al. 2000; Geraci and Lounsbury 2005; Gulland et al. 1997).

Anthropogenic threats include human interaction (e.g., fishery entanglement or legal shooting), ocean contamination (e.g., organic contamination and trash pollution), territory encroachment or loss of habitat, and ocean contamination in the form of trash and organic pollution that lead to fatal skin diseases (Beckmen et al. 1997; Folkens and Reeves 2008; Geraci and Briggs 2007). However, infectious diseases are always evolving just like their hosts. Notably, population development near human-associated regions can allow for transfer of disease where there was no prior concern for such predating the bottlenecking event (Brownell et al. 2000).

General pinniped pup survival rate is low within their first year (Geraci and Lounsbury 2005). Whether it be due to mother inexperience, overcrowding, or weather events, primary cause of newborn death is accidental separation or early desertion from the mother, the cascading results of which being targeted by predators, trampling from adult males, and eventually starvation (Le Boeuf and Briggs 1977). A pup has a higher likelihood of death when its harem, or group of females that bred with a single male, is larger (Le Boeuf and Briggs 1977). Death rates in seals are very high in pups and juveniles. This decreases with age into adulthood and then will eventually increase as old

age and its accompanying complications come into play (Geraci and Lounsbury 2005).

## Physiology

Elephant seals undergo what is called a catastrophic molt, meaning that instead of only shedding fur, the top, epidermal layer of skin will detach in mats with the fur on top (Ling 1978). Molting happens in late summer to autumn for southern elephant seals and takes up to a month to complete. The seals will haul out on shore at a safe location and stay there for the entirety of their molt (Folkens and Reeves 2008). Molting season occurs in spring and early summer months for northern seals, earlier for the females and juveniles, then later for the males. Northern seals do not engage in much activity during actual molting. Aggregated groups will huddle together and pass most of the molt sleeping (Folkens and Reeves 2008). After a recent molt, pelage of adults will take on a silver sheen, pups, too, after weaning (Folkens and Reeves 2008). Within several weeks, this coloring will change to the characteristic tan or dark brown (Folkens and Reeves 2008).

They also have special internal adaptation to regulate their body temperature and circulatory system for deep diving. They can hold their breath for up to 2 h, though standard foraging dives last around half an hour, by inducing bradycardia, a slowing of the heart rate (Folkens and Reeves 2008). Elephant seals are so adept at warming their bodies for underwater conditions; they have a greater chance of overheating on land (Noren 2002).

## Reproduction

Both species of elephant seal are extremely polygynous, meaning that one male will breed with many females, and breeding season occurs once a year (Folkens and Reeves 2008). Adult males will make landfall before the females, who are pregnant from the previous year's mating. They will give birth after spending a week on land. Pups

will be weaned and self-sufficient within 3 to 4 weeks, having grown nearly five times their weight at birth (Folkens and Reeves 2008; Le Boeuf and Briggs 1977). Males will challenge each other through vocal and physical posturing for the right to mate with females (Folkens and Reeves 2008). When posturing aggressively against other competitors, males will inflate their snouts to emit roaring vocalizations (Folkens and Reeves 2008). Damage from teeth can be extensive but not usually fatal. A hierarchy is created based on these confrontations and the relative size and age of the present males (Folkens and Reeves 2008). While young males may become sexually mature, they may not achieve successful mating for years later (Geraci and Lounsbury 2005). If a male does not achieve enough rank status, he will not be allowed to mate with any females. While the breeding season haul out is still enacted, the established hierarchy will remain in place through vocal reinforcement of the most dominant males (Folkens and Reeves 2008). When mating is over, adults will return to their ocean habitats to forage for food. Females will need to regain weight lost through pup bearing and milk production. Newly weaned pups must fend for themselves (Folkens and Reeves 2008).

Seals are capable of a neat trick called delayed implantation. It allows them to mate, undergo egg fertilization, and then delay the fertilized egg from attaching to the uterine wall by causing temporary dormancy, thereby suspending embryo development until the mother is able to physically and nutritionally withstand the pregnancy and hormone levels promote the continuation of the pregnancy and time of the birth of the offspring to coincide with the next year's haul out period (Geraci and Lounsbury 2005). This is known as obligate diapause. It enables the successive pairing of birthing and mating periods, therefore limiting the amount of time individuals need to be out of their foraging habitats (Geraci and Lounsbury 2005).

Before mating can begin, males of both species will develop a hierarchy of dominance to determine who can mate with females. Vocal threats used by males in these challenges are called "clap-threats" and resemble a clapping sound (Folkens

and Reeves 2008). They are deafening and can reach for miles. Juvenile males may play-fight to practice using the same posturing, rearing their head and chests with mouths open.

Southern seals breed in the months of October and November (McConnell et al. 1992). After molting, the birthing and breeding periods occur subsequently, and respectively, during the same haul out (CDC). Gestation can last for 10 months.

The height of northern seal breeding season occurs in January and occurs in regions of Baja California and Oregon (Le Boeuf and Briggs 1977; Le Boeuf as cited in Le Boeuf and Laws 1994). Females typically give birth midwinter, in mid-December or early January (Le Boeuf and Briggs 1977). For 28 days, they care for and nurse their newborn pups, fasting the whole time (Le Boeuf and Briggs 1977). Concurrently, females will also bite and vocalize to ward away other pups and females in the event of wayward milk-stealing or feeling that their own pup is being threatened (Folkens and Reeves 2008; Le Boeuf and Briggs 1977). Twins and adoptions are possible but rare, due to the high-energy cost of pregnancy and nursing (Le Boeuf and Briggs 1977). Gestation lasts 11 months in northern seals (Folkens and Reeves 2008). After this time of nursing, females will mate with a dominant male and promptly leave their newly weaned young to forage in the ocean and regain lost fat stores.

## Conservation Status

Northern elephant seals underwent a severe bottlenecking event due to hunting in the 1800s (Brownell et al. 2000). They were commercially hunted thoroughly in the 1800s that they were believed extinct (Folkens and Reeves 2008). Population numbers have steadily risen since the hunting termination. Instances of such astounding rebounds are uncommon (Stewart et al. 1994). This resulted in the limitation of genetic diversity of the species. However, the population sizes have been estimated to have recovered from less than 100 animals to close to 130,000 (Le Boeuf and Laws 1994).

Threats to elephant seals are led by habitat loss from pollution and climate change and decrease in prey species availability. Natural predators of the

northern elephant seal are no longer as widespread terrestrially, and laws have recently been adopted that protect seals and their habitats. These are leading reasons for the recent regrowth of northern populations (CDC).

Aboriginal uses for seals included sources for clothing material, food, and tools (Folkens and Reeves 2008). Aboriginal and indigenous people traditionally hunted elephant seals for hundreds, if not thousands, of years (Folkens and Reeves 2008). The population reached its lowest numbers in the 1800s and 1900s when sealing was a commercial business spurred by demand of blubber for its many uses. Sealing ended in the 1960s, concurrently with whaling that took place along shorelines (Folkens and Reeves 2008). In 1972, the Marine Mammal Protection went into effect in the United States. The Convention for the Conservation of Antarctic Seals was globally implemented in 1978. These regulations prohibit the interference with and hunting or capture of seals and other marine mammals, with some exceptions. According to stock assessments conducted by the National Oceanic and Atmospheric Association, which do not include southern elephant seals, northern elephant seal populations have shown increases since their enforcement (National Oceanic and Atmospheric Association 2015). Elephant seals are currently categorized under least concern regarding their conservation status as of 2014 (Hofmeyr 2015).

Department of Anthropology and Archaeology,  
University of Calgary, Calgary, AB, Canada

## Introduction

Elisabetta Visalberghi (Senior Research Associate, CNR) retired in 2017 from the position of Research

Director at the Istituto di Scienze e Tecnologie Cognizione of the Consiglio Nazionale delle Ricerche (CNR) in Rome, Italy. She is best known for her contributions to our understanding of primate cognition, particularly in the areas of tool use, responses to novel foods, and social influences on learning. Both her experimental techniques in the laboratory and her observational/documentary methods in the field have established approaches to animal cognition that have been innovative and influential.

### **Overview of Dr. Visalberghi's Academic Career and Major Contributions**

Born in Aosta, Italy in 1952, Visalberghi studied at the University of Rome and then at the Scuola Normale Superiore of Pisa under the supervision of Professor Floriano Papi, a renowned ethologist. Although Visalberghi is one of the world's foremost experts on capuchin monkeys, she has also studied other species such as homing pigeons, rats, wolves, titi monkeys, squirrel monkeys, and chimpanzees.

Throughout her career, Visalberghi has published extensively in a variety of high quality journals and edited volumes. As of 2017, she has published seven single and co-authored books, 146 journal articles, 52 book chapters, and an additional 20 articles in Italian journals. She is a frequent consultant on television and radio programs, has acted as a scientific advisor to several public institutions, has been a visiting scientist at academic institutions in Brazil, Germany, Japan, Ivory Coast, Guinea Conakri, and the United States, and is the former President of the Italian Ethological Society and the Italian Primatological Association and Secretary General of the International Primatological Society. Over the course of her career, she supervised 49 theses to completion (31 Laureates, 7 Masters, 11 PhDs).

Visalberghi began her academic career in ethology with a thesis on the cryptic and warning colorations of grasshoppers. From there she went on to study navigation in homing pigeons and neophobia in rats. However, a turning point came early in her career when she was invited to

establish a small primate center for the CNR inside the Rome Zoo. Determined to train herself first in primatology, she won a NATO fellowship to study at the California Primate Centre. It was there, working with titi and squirrel monkeys under the supervision of the experienced primate psychologist William Mason, that Visalberghi designed the first of her long line of inventive and effective laboratory experiments to elucidate how monkeys solve problems (Visalberghi and Mason 1983).

When Visalberghi returned to Rome, she started to study the capuchin monkeys she obtained for the newly established Primate Center and began her lifelong focus on their cognitive abilities, an interest prompted by her first experiment on capuchin tool use (Antinucci and Visalberghi 1986). It was in this period that Visalberghi met and began her lifelong teamwork with Dorothy Fragaszy, who also focuses on the cognitive abilities of capuchins. In the 1980s, they began a productive and continuing collaboration of designing experiments for captive capuchins that examine the tool using capacities of these monkeys as a window into the functioning of their minds.

Two particularly significant experimental contributions developed by Visalberghi are called the "tube task" in which the subject must learn how to acquire a food item out of a clear tube by pushing it through with the appropriate tool from a variety of options and the "trap-tube test" in which the subject needs to avoid the hazard of the trap (Visalberghi and Limongelli 1996; Fragaszy et al. 2004) by choosing into which side of the tube to insert the tool. Visalberghi has performed these experiments separately with capuchins, chimpanzees, and human children and compared their performances. Results indicate that all species learn to select and use the correct tool, but do so at different speeds. In particular, capuchins need more extensive experience to appreciate what makes a tool effective. Visalberghi also tested whether naïve individuals of the three species can take advantage of observing a proficient individual solving the tube task. She found that adult capuchins were unable to replicate the model's behavior with the tool shortly after

observing the proficient individual. In contrast, when chimpanzees above a certain age, and even more so children above a certain age, observe a proficient model, they more quickly acquire the new behavior. Finally, in the “trap tube task,” some chimpanzees and most children above 3 years of age were able to appreciate the consequences of pushing the reward in such a way as to avoid the trap, whereas capuchins were not, unless they could use another arbitrary predictive cue (see ► “Trap-Tube Problem” in cross-references). The results of these and many other experiments led Visalberghi to her signature conclusion that monkeys do not learn complex behaviors by imitation but rather by trial and error in a social context that facilitates acquisition of the new behavior. She and Frigaszy have published numerous articles on socially biased learning, continuing through their most recent paper in PNAS (Frigaszy et al. 2017). Their more recent studies on wild capuchins who have many years of experience using stone tools to crack open palm nuts proved that capuchins can acquire stone tool-using skills resembling those of wild chimpanzees. Since these behaviors have been considered sophisticated only when chimpanzees perform them and field observations are not powerful enough to disambiguate this issue, Visalberghi and co-authors proposed creative field experiments (Visalberghi et al. 2015).

From her years of examining the tool-using abilities of captive capuchins, Visalberghi had predicted that capuchins in the wild would be most likely to use tools in an environment where they spent a lot of time on the ground and where there would be an availability of hard-shelled nuts and appropriate stones that can function as hammers and anvils (Visalberghi 1987). In 2004, Visalberghi and Frigaszy, and colleagues Patricia Izar and Eduardo Ottoni, found precisely such a site – Fazenda Boa Vista in northeastern Brazil. In 2005, the “EthoCebus” research team began to study the behavioral ecology of the bearded capuchins (*Sapajus libidinosus*) living in an open woodland habitat, where these monkeys routinely use stones to crack open palm nuts that they have placed on stone or wood anvils (<http://EthoCebus.net>). The work of this research team has resulted

in an outpouring of notable scientific publications on how and why these monkeys are such prolific and successful tool users (e.g., Visalberghi et al. 2005, 2009, 2015) plus a great deal of popular science press and attention. Though counterintuitive, they found that the routine tool use of these monkeys is not due to food scarcity (Visalberghi and Frigaszy 2013). Their images and video footage of capuchins strategically placing nuts on anvils and lifting heavy stones to shoulder or head height and then pounding the stones down on the fruits (actions that look similar to the “clean and jerk” move of weight lifters) is so eye-catchingly remarkable as to have been exhibited on the covers of several journals and books, and repeatedly shown in the popular scientific media. In 2012/2013, Visalberghi and Alessandro Albani made a documentary on the bearded capuchin monkeys of Fazenda Boa Vista, a film that they regard as a needed correction to the less rigorous/scientific interpretation of primate behavior that is typical of most nature documentaries. Their documentary, called “The Bearded Capuchin Monkeys of Fazenda Boa Vista,” has won several awards. The trailer and information can be found at: <http://www.ucp.istc.cnr.it/index.php/news/124-the-bearded-capuchin-monkeys-of-fazenda-boavista>

## Conclusion

In recognition of her outstanding achievements in research, Visalberghi has won numerous awards, such as the Frassetto Award for Physical Anthropology from the Italian Academy of Science, the Prix Geoffroy Saint-Hilaire given by the French Society for the Study of Animal Behavior, and the Career Award from the Italian Primatological Association. There are other aspects of Visalberghi’s research interests, such as capuchin sexual behavior, facial displays, responses to novel foods, social influences on food consumption, action synchronization, and affiliation (many of these projects carried out in collaboration with her students) that have resulted in important insights into primate behavior. But the enduring characteristic of her work is that she begins with

careful observation of the animal and then applies various ingenious experiments to illuminate how the animal solves problems, learns new tasks, and is affected by controlled variables. And she is willing to defend a parsimonious interpretation even when her findings are counterintuitive to popular assumptions and prevalent scientific views. Her empirical, inductive approach has led to a wealth of new understandings in the field of primate behavior and cognition that will surely stand the test of time.

## Introduction

Psychology's mid-twentieth century cognitive revolution viewed thinking as information processing. This information processing hypothesis was inspired by the digital computer, and by

demonstrations that this new device could perform many tasks that were assumed to require intelligence (Feigenbaum and Feldman 1963). In other words, when cognitive psychologists hypothesize that cognition is information processing, they view “information processing” as being analogous to the operations of a digital computer: the rule-governed manipulation of stored information. Traditional cognitivists therefore assume the existence of mental representations and presume that thinking is manipulating these representations using a mental programming language (Fodor 1975; Gardner 1984).

In general, traditional theories elaborate this view of cognition into a three stage process. First, information from the environment is sensed. Second, this information is used to construct a model of the external world (i.e., a mental representation of the world) that can then be manipulated to plan actions to perform. Third, once an appropriate plan of action is developed (and once inappropriate plans are discarded), this action is executed. Thus, cognition is treated as a sense-think-act cycle called the classical sandwich (Hurley 2001) because thinking is sandwiched between sensing and acting. According to the classical sandwich, thinking necessarily stands between sensing and acting: one cannot act without first thinking, and that the purpose of thinking is to plan action. Importantly, while the classical sandwich assumes three different processing stages, traditional cognitive theories almost invariably emphasize the “thinking” stage, and underemphasize “sensing” or “acting” (Dawson 2013).

Traditional cognitivism has led to many successful theories and is the dominant school of thought within psychology and cognitive science. However, this approach has also faced many setbacks. Cognitive theories of human thinking, or computer simulations of human cognition, have often been successful for simple or small problems but have performed poorly when scaled up to deal with more complicated situations (Dreyfus 1972, 1992). In domains where real-time action on the world is critical, such as robotics, traditional theories are often flawed because they encounter a “thinking bottleneck: Far too much

time is spent updating and manipulating a representation of the world before actions are performed (Brooks 2002). Some have argued that traditional cognitivism’s emphasis on internal representations prevents it from developing adequate accounts of phenomena like understanding language, because such phenomena arise from rich interactions between the bodies of agents and the ways in which these bodies can sense and act upon the world (Winograd and Flores 1987).

Such problems have led some researchers to develop new perspectives on cognition that adopt assumptions that are radically different from those adopted by traditional cognitivism. Embodied cognition is one such reaction (Clark 1997; Dawson 2013; Dawson et al. 2010; Shapiro 2011). The purpose of this article is to introduce the major characteristics of embodied cognition and to contrast these characteristics with the basic assumptions of traditional cognitivism.

## Characteristics of Embodied Cognition

In very general terms, the theories of embodied cognition depart from those of traditional cognitivism by considering cognition to be a sense-act cycle instead of a sense-think-act cycle. This departure has two crucial consequences. First, there is a move away from emphasizing mental representations. This is because the external world is viewed as its own representation; it is accessed by being sensed instead of being modeled in the mind. Second, there is a move towards emphasizing sensing and acting. This in turn requires considering the rich relationship between both the world and the agent. How the world can be sensed, and how it can be manipulated, depends crucially on the structure of an agent’s body.

While traditional cognitivism aims to explain complex behavior by appealing to the complexities of mental representations, embodied cognition is more likely to explain complex behavior as emerging from the complexities of the environment interacting with (simpler) properties of an agent. Let us briefly consider some of the key

assumptions that provide the foundation for embodied cognition.

### Environment

One key characteristic of embodied cognition is its recognition of the importance of the environment. While traditional cognition explains complex behaviors by appealing to complex mental representations, embodied cognition recognizes that environmental properties are critical contributors to this complexity. This is perhaps best reflected in Herbert Simon's parable of the ant (Simon 1969). To explain the complex shape of an ant's path as it moves along a beach, Simon famously noted that "viewed as a geometric figure, the ant's path is irregular, complex, hard to describe. But its complexity is really a complexity in the surface of the beach, not a complexity in the ant" (Simon 1969, p. 24).

The parable of the ant is nicely illustrated by the 1940s autonomous robot, called the Tortoise, invented by William Grey Walter (Grey Walter 1950, 1963; Holland 2003a, b). The Tortoise displayed a variety of complex, life-like behaviors. The Daily Mail reported that "the toys possess the senses of sight, hunger, touch, and memory. They can walk about the room avoiding obstacles, stroll round the garden, climb stairs, and feed themselves by automatically recharging six-volt accumulators from the light in the room. And they can dance a jig, go to sleep when tired, and give an electric shock if disturbed when they are not playful" (Holland 2003a, p. 2090).

However, such varied behavior was not produced by complicated internal mechanisms. The internal structure of the Tortoise was surprisingly simple: two sensing mechanisms, one for light and the other for physical contact, controlled two motors, one for moving and the other for steering. As the values detected by the sensing mechanisms changed, so too did the speeds of the two motors. The complexity of Tortoise behavior emerged from interactions between these simple mechanisms and the Tortoise's environment (e.g., light sources, obstacles). To generate more complex behavior, Grey Walter left the Tortoise's internal mechanisms unaltered and instead increased the complexity of the robot's environment by adding

multiple light sources, new obstacles, obstacles that reflected light, moving sources of light, and so on.

Importantly, one reason that complex behavior can emerge from the interactions between a complex environment and a simple agent is the fact that these interactions are generally nonlinear. For example, there is a nonlinear relationship between light level and steering motor speed in Grey Walter's Tortoise. In low light, the steering motor runs slowly; in medium light, the steering motor stops; in bright light, the steering motor runs at a higher speed.

### Situatedness and Embodiment

If complex behavior emerges from the nonlinear interactions between the world and the environment, then additional assumptions must follow. First, agents must be able to sense properties of the environment. In embodied cognition, this ability is called *situatedness*. As the sensors of an agent become more sophisticated, or greater in number and variety, the agent will become capable of producing more and more complicated behavior provided that it is placed in an interesting environment (Braitenberg 1984). In this context, an interesting environment is an environment in which various qualities that can be sensed are distributed unevenly.

In embodied cognition, agents are considered to be *situated* – and not merely as "sensing" – because their ability to respond to properties of the environment is fundamentally related to the structures of their bodies. *Situatedness* is closely related to the early twentieth century theoretical biology of Jakob von Uexküll. He coined the term *umwelt* to denote the "island of the senses" produced by the unique way in which an organism is perceptually engaged with its world (Uexküll 2001). Von Uexküll realized that because different organisms experience the world in different ways, they can live in the same world but at the same time exist in different *umwelten*. One can only describe an *umwelt* by describing the properties of both a world and an agent. For instance, it can be easily demonstrated that the behavior of a simple robot can be changed by repositioning its light sensors by moving them further away from

the center of the agent, or by changing their physical orientation (Dawson et al. 2010). Furthermore, in embodied cognition it is frequently assumed that agents actively explore their world to seek out new information as it is needed (Noë 2004); the nature of such exploration depends upon the structure of agents' bodies.

A second assumption that follows from the view that complex behavior emerges from the interactions between agents and environments is that agents must be embodied. To say that an agent is embodied is, in the most general sense, simply to say that the agent is physically present in the world. More sophisticated notions of embodiment drive embodied cognition. It can be argued that there is a continuum of embodiment, and that even if an agent physically exists this does not mean that it is completely embodied. Instead, embodiment is reflected in the degree to which the agent can affect or manipulate its environment (Fong et al. 2003). The more embodied an agent is, the more it can alter the world in which it is situated.

This notion of embodiment is therefore strongly related to Gibson's ecological theory of perception (Gibson 1979). Gibson's theory relied upon the coupling between an agent and the world, and emphasized that this coupling depended upon the nature of an agent's body. "It is often neglected that the words *animal* and *environment* make an inseparable pair" (Gibson 1979, p. 8). One reason for this was because Gibson's theory was an argument that the purpose of perception was to deliver affordances. Affordances are the possibilities for action that a particular object permits a particular agent. Affordances require an integral relationship between an object's properties and an agent's ability to act on these properties. Furthermore, an agent's ability to act depends upon the structure of its body. In short, an affordance must be defined in relation to an agent's body.

In short, in embodied cognition's emphasis on situatedness and embodiment, we see modern researchers endorsing two older notions, *umwelt* and affordance, as they emphasize the dynamic, nonlinear relationship between agents and their environments.

## Feedback

In embodied cognition, agent behavior is driven by sense-act connections based upon situatedness and embodiment. An agent is viewed as being embedded in a dynamic relationship with its environment; its environment triggers particular actions from the agent. Importantly, if an agent's actions can change the world, then these changes in turn can influence the agent's future actions. Cyberneticists called this dynamic relation between agents and environments feedback (Ashby 1956; Wiener 1948). Ashby (1956, p. 53) noted "'feedback' exists between two parts when each affects the other," when "circularity of action exists between the parts of a dynamic system." Feedback is an important source of behavioral complexity in embodied cognition, particularly in cases where an agent's environment includes other agents.

For example, consider the dynamics of a bat pursuing a moth. Many species of bats hunt by emitting ultrasonic sounds and by using their echoes to detect the location of targets. This enables bats to detect and to intercept targets as small as fruit flies or mosquitoes from distances of between 50 and 100 cm (Griffin et al. 1960). However, moths do not passively wait to become meals. Some moths have evolved transducers that permit them to hear bat echolocation signals (Fenton and Fullard 1979; Roeder and Treat 1961; Rydell et al. 1995). As soon as such a signal is heard, a moth will execute a power dive towards the ground; this dive often includes a series of evasive maneuvers that involve tight turns, loops, and climbs (Roeder and Treat 1961). In addition, some moths emit their own ultrasonic sounds to cause bats to turn away from their prey (Dunning and Roeder 1965). In short, bats and moths are clearly in a feedback relationship with their environment. The bat's actions – both in terms of its flight and in terms of the kinds of sounds that it generates – depend upon the distance between the bat and its prey. Furthermore, when a moth detects this attack, it begins evasive maneuvers, which represents a change in the world caused by the bat's ultrasonic probing. In turn, this change in the world produces changes in the bat's behavior, as it alters its flight path to foil

the evasion. The feedback relationship between these two agents – which are each dynamic components of the other's environment – is required to explain the complexity of the behavior of either agent as predator pursues prey.

It is important to note that the dynamic interactions between bats and moths occur over exceedingly short periods of time. Bats are usually hunting targets that are less than a meter away, are flying speeds of 1–6 m/s, and have only a few milliseconds to process the echo from any given target (Horiuchi 2005). Embodied cognition researchers would argue that bats simply do not have time to construct a mental model of their world to be used to plan the trajectory of their pursuit. Embodied cognition's emphasis on sense-act processing is to eliminate the "thinking bottleneck." "Models of the world simply get in the way. It turns out to be better to use the world as its own model" (Brooks 1991, p.139).

### Sense-Act Mechanisms

The notions of situatedness, embodiment, and feedback are all tied into embodied cognition's emphasis on sense-act processing as an alternative to traditional cognitivism's preference for the sense-think-act cycle. As a result, it is not surprising that embodied cognition seeks support for its position by discovering evidence for neural mechanisms that directly link sensing to acting.

For one example, neuroscientists studying bat echolocation have discovered a circuitry that is consistent with sense-act processing. Auditory processing in the bat brain is tightly coupled with motor processing, particularly with motor circuits responsible for bat vocalizations (Moss and Sinha 2003). This might reflect a sense-act system for modulating ultrasonic signals as a function of echolocation feedback.

Cognitive neuroscientists are also providing evidence for existence of sense-act mechanisms in the human brain (Goodale and Humphrey 1998). Goodale and Humphrey argue that the dorsal stream in the human brain, with connections from visual cortex to parietal cortex, mediates the visual control of action. They propose that the dorsal stream converts visual information directly into motor commands. This proposal is

supported by double dissociation evidence obtained from clinical patients. Patients with damage to their ventral stream are unable to describe the orientation or shape of any visual contour (Goodale et al. 1991). However, while this information could not be consciously reported, it was available and could control actions. The patient could grasp objects, or insert objects through oriented slots, in a fashion indistinguishable from control subjects, even to the fine details that are observed when such actions are initiated and then carried out. In contrast, damage to the posterior parietal cortex – part of the dorsal stream – can cause optic ataxia, in which visual information cannot be used control actions towards objects presented in the part of the visual field affected by the brain injury (Jakobson et al. 1991). Optic ataxia, however, does not impair the ability to the orientation and shapes of visual contours.

### Scaffolding and Control

Embodied cognition views agents as being dynamically embedded in environments and as being capable of acting upon and altering their worlds. The ability to change the world permits agents to use their environment to support or extend cognition. Using the world in this way is called cognitive scaffolding. For instance, using external devices (pens and notebooks, computers, etc.) to take notes during a lecture demonstrates the scaffolding of memory. More elaborate examples of scaffolding come from studies that examine practical problem solving activities in real world environments.

One famous example is Sylvia Scribner's study of problem-solving strategies exhibited by different types of dairy workers (Scribner and Tobach 1997). For example, workers assembled orders by converting information from computer printout into the required number of cases and partial cases of dairy products to be loaded onto each truck. However, the printout represented an order's information in a format that required the worker to convert it into more practical numbers of to-be-loaded products. Scribner found that novice workers solved this problem using mental arithmetic. In contrast, expert workers scaffolded the solution of this problem by working directly

from the visual appearance of cases of dairy products. One of the expert participants in this study reported that “I walked over and I visualized. I knew the case I was looking at had ten out of it, and I only wanted eight, so I just added two to it ... I don’t never count when I’m making the order, I do it visual, a visual thing you know” (Scribner and Tobach 1997, p. 303).

The external world can not only be used to store information but can also be used to manipulate it. Examples of this are provided by a variety of navigational tools that permit the results of computations to simply be inspected after data is recorded on them (Hutchins 1995). “It seems that much of the computation was done by the tool, or by its designer. The person somehow could succeed by doing less because the tool did more” (Hutchins 1995, p. 151).

There are also interesting examples in which computations are performed by the shapes of agent bodies. For instance, let us briefly return to bat echolocation. With echolocation, the horizontal position of a prey insect is uniquely determined by the difference in time between the echo’s arrival to a bat’s left and right ears. However, this information is not sufficient to uniquely specify the vertical position of the target. Evidence suggests that the extravagant shapes of the pinna and tragus of bats external ears are important for computing a target’s vertical position. These shapes cause returning echoes to strike the ear at different angles of entry, causing specific distortions in the sound signal (Muller et al. 2008; Obrist et al. 1993; Reijniers et al. 2010). These distortions provide additional auditory cues that vary systematically with the vertical position of the target (Wotton et al. 1995; Wotton and Simmons 2000). In other words, the shape of a bat’s ear alters sound in such a way that information about a target’s vertical dimension is added to the incoming signal. The bat’s body computes a solution to the vertical positioning problem before sound signals even reach the bat’s brain.

Finally, scaffolding also provides an external means of systematically controlling action to achieve complex goals. For instance, entomologists have long been interested in explaining how

social insects can build large and complex structures such as termite mounds. One important idea about the “plan” for the construction of social insect nests is the notion of *stigmergy* (Grasse 1959; Theraulaz and Bonabeau 1999). With stigmergy, the actions of a group of agents are controlled via a shared environment. Environmental cues cause an agent to act upon and change the world. These changes in turn alter the later actions of this agent, or those of other members of an insect colony. Grassé’s notion of stigmergy is the proposal that termite building behavior is not planned or regulated by the insects themselves but is instead controlled externally by the changing appearance of the mound.

### The Extended Mind

We have seen that one consequence of embodying cognition is that an agent’s environment can be actively exploited or modified to scaffold cognition. This in turn leads to a radical and controversial hypothesis: that the mind extends into the world (Adams and Aizawa 2008; Clark 1997; Clark and Chalmers 1998; Wilson 2004). According to the extended mind hypothesis, the mind and its information processing is not separated from the world by the skull. Instead, the mind interacts with the world in such a way that information processing is both part of the brain and part of the world – the boundary between the mind and the world is blurred, or has disappeared.

Where is the mind located? The customary view – typified by traditional cognitivism – is that thinking is inside the individual, and that sensing and acting involve the world outside. However, if cognition is scaffolded, then some thinking has moved from inside the head to outside in the world. “It is the human brain *plus* these chunks of external scaffolding that finally constitutes the smart, rational inference engine we call mind” (Clark 1997, p. 180). As a result, Clark describes the mind as being extended, because it spreads from inside our skull to include whatever is used as external scaffolding. In other words, one key difference between traditional cognition and embodied cognition concerns where minds are located.

## Conclusion

Traditional cognitive theories emphasize sense-think-act processing, presuming that the purpose of cognition is to construct models of the external world that can be used to plan future behavior. Embodied cognition is a reaction against this view and assumes that mental models of the external world are not required, because the world can serve as its own model. Embodied cognition therefore attempts to replace the sense-think-act cycle with sense-act processing that permits the world to directly control action. This view places a greater emphasis on the nature of the environment, and on the structure of agents' bodies, than is found in traditional cognitivism. Agents are taken to be situated and embodied in an environment. What can be sensed in the environment, and how the environment can be altered by agents, depends critically on the interaction between worlds and bodies. The complex behaviors of agents may be explained by appealing to feedback between agents and environments that are mediated by sense-act mechanisms, and which permit critical components of the mind to extend into the world by means of cognitive scaffolding.

## Synonyms

Action perception; Enactive perception

## Introduction

Embodied perception, sometimes called enactive perception, reacts against the traditional view that the purpose of perception is to construct mental representations of the external world. Embodied perception does this by adopting a key position of behavior-based robotics: that it is unnecessary to create costly mental representations of the world when the world can serve as its own representation (Brooks 1999, 2002). Embodied perception further argues that perception is not a representational process but is instead a motor skill concerned with actions upon the world (Noë 2004, 2009). This casts embodied perception as a modernization of James Gibson's ecological approach (Gibson 1966, 1979).

This entry introduces embodied perception. It begins by briefly describing the main assumptions underlying traditional, representational, theories of perception. It then uses problems associated with these assumptions to introduce the properties of theories of embodied perception. Different kinds of evidence supporting these assumptions are briefly reviewed, as are the links between embodied perception and some modern theories of vision.

## Against Representational Theories of Perception

Our phenomenal experience of visual perception gives rise to a simple notion that seeing is like photography: the eyes transmit visual information

to an inner screen that is mediated by some spatial layout of neurons (Frisby and Stone 2010). Our everyday experience is that visual perception is effortless, that we simply look at the visual world and automatically experience its layout. This inner screen theory necessarily defines visual perception as a representational process. This is because whatever the nature of the “inner screen,” it differs from the visual world outside the head, and therefore must stand for or represent the world’s visual properties.

With the current prevalence of cognitive theories in psychology (Dawson 2013), the view that the purpose of visual perception is to create meaningful representations of the world is widely accepted (Marr 1982). This position in turn dictates that theories of visual perception must explain the nature of these representations and how they are created and manipulated. Explorations of perceptual representations have led to two different issues that have fueled research questions, but that have also produced reactions against this representational approach.

The first issue is that visual perception is underdetermined (Marr 1982). Visual perception can be conceived as beginning when a distal stimulus (the layout of surfaces in the external world) provides visual information that creates a proximal stimulus (such as a pattern of stimulation on the retinae). Cognitivism implies that the task of vision is to create a mental representation of the distal stimulus that caused the proximal stimulus. The problem, though, is that for a variety of reasons information about the distal stimulus is lost when the proximal stimulus is created (Grimson 1981; Hildreth 1983; Marr 1982; Richards 1988; Ullman 1979). This means that there is a poverty of the proximal stimulus: on its own it does not contain sufficient information to uniquely recreate the distal stimulus that produced it. In principle, the proximal stimulus by itself is consistent with an infinite number of different distal stimuli. Vision is underdetermined because there is not a one-to-one mapping from a proximal stimulus to a distal stimulus.

Many different representational theories have arisen to deal with the problem of underdetermination. These theories propose

various means by which information missing from the proximal stimulus can be added by additional processes in order that a unique and correct representation of the visual world can be constructed. These theories range from the top-down addition of knowledge of the world (Bruner 1957, 1992; Gregory 1970; Rock 1983) to the bottom-up application of natural constraints (Marr 1982; Richards 1988; Ullman 1979).

Importantly, the additional processing that is required to create unique representations from underdetermining proximal stimuli leads to a second key issue: that creating representations of the distal world is costly. The relevance of this issue was revealed in early research on autonomous robots, machines that navigated by planning routes and actions by using representations of the world (Brooks 2002; Moravec 1988; Nilsson 1984). In general, these machines were stationary most of the time they were operating because they were busy updating and manipulating their internal representation of the world to plan actions before these actions could be carried out. Brooks (2002) has noted that one famous robot, Nilsson’s Shakey, would take hours to move to a goal location a few meters from its starting position. “Most of the time Shakey, the robot shell, sat idle while its remote brain contemplated a long series of moves to accomplish its ultimate goal” (Brooks 2002, p. 23).

Brooks’ response to this problem was to abandon representations. He developed robots that did not require internal models of the sensed world. Instead, these robots directly converted sensed information into actions upon the world, making the behavior of these robots fast, responsive and adaptive. This approach has been called behavior-based robotics or new wave robotics (Brooks 1999; Sharkey 1997). The defining feature of this approach is replacing representation with reaction; embodied perception is also characterized by this feature. Accordingly, visual perception becomes construed as a sensorimotor skill that accesses information in the world as it is needed. Rather than building detailed internal models of the world, embodied perception – like behavior-based robotics – considers the world to be its own representation; we don’t construct an

internal model of the world, because we can act upon the outer world, and inspect it, when required (Noë 2002, 2004, 2009).

Embodied perception involves more than merely assuming that information in the world is inspected, and not represented. It also abandons representations because it assumes that perception has a quite different goal: guiding bodily actions upon the world. “Perceiving is a way of acting. Perception is not something that happens to us, or in us. It is something we do” (Noë 2004, p. 1). This view of perception arises because embodied theorists are inspired by Gibson’s ecological approach to perception as is discussed later (Gibson 1966, 1979).

Acting upon the world plays multiple roles in the theory of embodied perception (Noë 2004). First, the purpose of perception is not viewed as building internal representations of the world, but instead as controlling action on the world. Second, and related to the importance of controlling action, our perceptual understanding of objects is sensorimotor, much like Gibson’s (1979) notion of affordance, as is discussed below. That is, we obtain an understanding of the external world that is related to acting on an object, or by moving to a new position. Third, perception is presumed to be an intrinsically exploratory process. Perceptual objects are virtual – we have access to properties in the world when needed, and only through action. “Our sense of the perceptual presence of the cat as a whole now does not require us to be committed to the idea that we represent the whole cat in consciousness at once. What it requires, rather, is that we take ourselves to have *access*, now, to the whole cat” (Noë 2004, p. 63).

## Evidence for Embodied Perception

Clearly there are dramatic differences between the basic assumptions of embodied perception and those found in more traditional representational theories. The discussion in the previous section highlights some of the theoretical motivations for the new sets of assumptions that are adopted in the study of embodied perception. There is also growing empirical evidence that supports these

assumptions. The purpose of this section is to briefly provide some examples of such support.

Representational theories of visual perception seem plausible because we experience our visual world as a rich, stable panorama that is present in its entirety. However, this experience is illusory. Evidence suggests that we only experience fragments of the distal world a glance at a time, which is consistent with the basic assumptions of embodied perception (Noë 2004, 2009).

One example of evidence that our perceptual experience is fragmentary is that we are subject to change blindness, and fail to notice substantial visual changes even though they occur in plain sight (O’Regan et al. 2000). We are also prone to a related phenomenon, inattention blindness, in which we do not detect obvious visual information because our attention is not directed to it. Inattention blindness is demonstrated by one famous experiment in which subjects watched a video of a basketball game, and counted the number of times that the teams changed possession of the ball (Simons and Chabris 1999). In the midst of the game, a person dressed in a gorilla suit walked out onto the court and danced a jig. Amazingly, most subjects failed to notice this highly visible event because they were attending to the ball.

Embodied perception not only assumes that perception is fragmentary (because it is not representational), but also assumes that there is a fundamental link between perception and action. This emphasis on actions on the world was also central to Gibson’s (1966, 1979) ecological theory of perception. Gibson proposed that perceiving agents “picked up” the affordances of objects in the world. Critically, the affordances of an object are the possible actions that a particular object makes available a particular agent. “The *affordances* of the environment are what it *offers* the animal, what it *provides* or *furnishes*, either for good or ill” (Gibson 1979, p. 127, his italics).

Crucially, the view that affordances are potential actions leads to the assumption that affordances emerge from an integral relationship between an object’s properties and an agent’s embodiment. This is because an agent’s embodiment defines its abilities to act. “Note that the four

properties listed – horizontal, flat, extended, and rigid – would be *physical* properties of a surface if they were measured with the scales and standard units used in physics. As an affordance of support for a species of animal, however, they have to be measured *relative to the animal*. They are unique for that animal. They are not just abstract physical properties” (Gibson 1979, p. 127).

Given that affordances are defined in terms of an organism’s potential actions, which in turn are defined by an agent’s embodiment, it would be expected that perceptions of the world can be affected by the states of an agent’s body, as well as by changes in these states. Evidence indicating that this is indeed the case provides additional support for embodied perception.

For instance, in a task where participants point to objects with their index finger versus pointing with a conductor’s baton, objects are viewed as being nearer in the latter condition (Proffitt 2006). Furthermore, Proffitt has also demonstrated that perception is also altered when changes in bodily state alter the cost of actions on the world. For example, slopes are viewed as being steeper, and distances are viewed as being longer, when one’s body is made heavier and therefore more costly to move. Similarly, the size of objects appears to be judged relative to the shape of body parts used to manipulate them (Linkenauger et al. 2011). Linkenauger et al. found that the apparent size of objects became smaller when participants experienced their hand size as being modified. Interestingly, such hand-size manipulations did not affect size perception when the object being judged was too large to manipulate with the hand. In a related study, when goggles are used to make the apparent size of objects larger or smaller, this apparent size modification vanishes when one reaches for an object with one’s hand – if the appearance of the hand is similarly modified (Linkenauger et al. 2010). However, the apparent size modification does not vanish if one views the object being manipulated by someone else’s hand, even if the appearance of this other hand is manipulated in the same way as the object.

It was noted earlier that embodied perception’s emphasis upon action links it to behavior-based robotics. Brooks’ robots are controlled by what he

calls the subsumption architecture (Brooks 1999). This architecture is a set of modules or operators that can each be described as a sense-act mechanism. That is, each module senses information in the world and then directly converts this information into action by altering the behavior of an actuator. Is there any evidence for this type of architecture in biological perceptual systems?

Evidence does suggest that sense-act modules that provide the foundation of the subsumption architecture also appear to exist in the human brain (Goodale 1988, 1990, 1995; Goodale and Humphrey 1998; Goodale et al. 1991; Jakobson et al. 1991). This has led to the duplex theory of vision (Goodale and Humphrey 1998). One characteristic of the duplex theory is its reworking of a standard perspective on the neuroscience of vision. According to this standard perspective, there exist two distinct physiological pathways in the human visual system, one (the ventral stream) for processing the appearance of objects, the other (the dorsal stream) for processing their locations (Livingstone and Hubel 1988; Maunsell and Newsome 1987; Ungerleider and Mishkin 1982). In contrast, the duplex theory proposes that while the ventral stream creates perceptual representations, the dorsal stream mediates the visual control of action in a fashion quite similar to the modules in Brooks’ subsumption architecture. “The functional distinction is not between ‘what’ and ‘where’, but between the way in which the visual information about a broad range of object parameters are transformed either for perceptual purposes or for the control of goal-directed actions” (Goodale and Humphrey 1998, p. 187).

Double dissociation evidence from cognitive neuroscience has been used to support the duplex theory. The study of one brain injured subject (Goodale et al. 1991) revealed normal basic sensation. However, the patient could not describe the orientation or shape of any visual contour, no matter what visual information was used to create it. While this information could not be consciously reported, it was available and could control actions. The patient could grasp objects, or insert objects through oriented slots, in a fashion indistinguishable from control subjects, even to

the fine details that are observed when such actions are initiated and then carried out. This pattern of evidence suggests that the patient's ventral stream was damaged, but that the dorsal stream was unaffected and controlled visual actions. "At some level in normal brains the visual processing underlying 'conscious' perceptual judgments must operate separately from that underlying the 'automatic' visuomotor guidance of skilled actions of the hand and limb" (Goodale et al. 1991, p. 155).

Other kinds of brain injuries produce a very different pattern of abnormalities, establishing the double dissociation that supports the duplex theory. For instance, damage to the posterior parietal cortex – part of the dorsal stream – can cause optic ataxia, in which visual information cannot be used control actions towards objects presented in the part of the visual field affected by the brain injury (Jakobson et al. 1991). Optic ataxia, however, does not impair the ability to detect the orientation and shapes of visual contours.

Healthy subjects can also provide support for the duplex theory. For instance, in one study subjects reached to an object whose position changed during a saccadic eye movement (Pelisson et al. 1986). As a result, subjects were not conscious of the target's change in location. Nevertheless, they compensated to the object's new position when they reached towards it. "No perceptual change occurred, while the hand pointing response was shifted systematically, showing that different mechanisms were involved in visual perception and in the control of the motor response" (Pelisson et al. 1986, p. 309). This again supports the existence of sense-act modules in the human brain. Similar evidence exists for other perceptual modes. For example, a great deal of evidence supports the claim that neural circuits for motor actions are critical components for the understanding of spoken and written language (Pulvermuller and Fadiga 2010).

The evidence cited above focuses upon the relationship between action and perception. The embodiment of an agent can affect perception in other ways as well. For instance, consider some evidence concerning how bats echolocate prey. Bats emit a high-frequency sound and detect the

location of targets by processing the echo (MacIver 2008). The horizontal position of a target (e.g., a prey insect) is uniquely determined by the difference in time between the echo's arrival to the left and right ears. However, this information is not sufficient to specify the vertical position of the target. The physical nature of bat ears solves this problem. The visible external structure (the pinna and the tragus) of the bat's ear has an extremely intricate shape. This shape causes returning echoes to strike the ear at different angles of entry. This provides additional auditory cues that vary systematically with the vertical position of the target (Wotton et al. 1995; Wotton and Simmons 2000). Furthermore, if the shape of the bat's ear is physically manipulated, then there is a substantial decrease in its echolocation abilities (Chiu and Moss 2007; Lawrence and Simmons 1982). In other words, the bat's body – in particular, the shape of its ears – is critical to its perceptual abilities.

## Integrating Representational and Nonrepresentational Theories of Perception

Embodied theories in cognitive science vary in their degree of radicalness. More radical embodied theories attempt to completely eliminate mental representations (Chemero 2009). Less radical theories combine both nonrepresentational and representational processes in an attempt to generate more complete, hybrid theories (Clark 1997). In certain respects, the growing acceptability of embodied perception is revealed by theories that attempt to integrate its nonrepresentational ideas with more traditional representational accounts of perception.

One such theory that we have already briefly encountered is the duplex theory (Goodale and Humphrey 1998). It is integrative in the sense that while the ventral stream in the human brain mediates traditional representational processing, at the same time the dorsal stream is presumed to implement sense-act modules of the type to be found in theories of embodied perception. In this section, we briefly consider another hybrid theory,

Zenon Pylyshyn's theory of seeing and visualizing (Pylyshyn 2003, 2007). The hybrid nature of this theory is intriguing because its author is a noted critic of a position that is central to embodied perception, Gibson's ecological theory (Fodor and Pylyshyn 1981). Discovering elements of embodied perception in Pylyshyn's theory provides strong evidence for the growing importance and acceptance of embodied ideas.

Pylyshyn's theory of seeing and visualizing emerged from his interest in explaining how diagrams were used in reasoning (Pylyshyn 2007). Pylyshyn recognized that a system for performing such reasoning required two core abilities: to be able to individuate visual entities and to be able to track or maintain the identities of visual entities over time. His account of these core abilities adds a strongly embodied flavor to his theory. He argues that one of the primitive processes of early vision is individuating a visual object as being distinct from others. In his theory, this is accomplished by preattentively tagging an object with an index called a FINST (for finger instantiation). A FINST only provides access to the individuated object, so that its properties can be inspected when needed. Once assigned to an object a FINST remains attached to it even as the object changes its location or other properties.

FINSTs individuate visual objects without delivering a description of them. Pylyshyn (2007) argues that this is the visual equivalent of using indexicals or demonstratives in language. "Think of demonstratives in natural language – typically words like *this* or *that*. Such words allow us to refer to things without specifying what they are or what properties they have" (Pylyshyn 2007, p. 18). FINSTs are visual indices that operate in exactly this way. They are analogous to placing a finger on an object in the world, and (while not looking) keeping the finger in contact with it as the object moved or changed (thus the term "finger instantiation"). As long as the finger is in place, the object can be referenced ("this thing that I am pointing to now"), even though the finger does not deliver any visual properties.

FINSTs are linked to embodied perception in two important ways. First, in traditional

representational theories of perception an object's features are first detected, and then the object is identified and individuated by combining these features into a description (Treisman 1986; Treisman and Gelade 1980). In contrast, in Pylyshyn's theory object individuation occurs before its features are processed or combined. In this sense, FINSTs are much less representational. Second, the purpose of a FINST is to provide access to an object in the world when needed, so that the properties of the object can be inspected when required. This is consistent with embodied perception's view that perception is fragmentary and that perceptual experience is constructed by examining parts of the world when needed.

There is a growing literature that provides empirical support for Pylyshyn's FINST hypothesis, which in turn provides additional evidence in support of embodied perception. Some of this evidence comes from a multiple object tracking paradigm in which a set of moving objects are treated as targets, and are indistinguishable from other moving distractors. Human participants are capable of tracking the target objects even when all of the objects move randomly through the visual field. This process is parallel, because up to four objects can be tracked, and tracking results cannot be explained by a model that shifts a spotlight of attention serially from target to target (Pylyshyn and Storm 1988). However, the fact that no more than four targets can be tracked also shows that this processing has limited capacity. FINSTs are assigned to objects, and not locations; objects can be tracked through a locationless feature space (Blaser et al. 2000). Using features to make the objects distinguishable from one another does not aid tracking, and object properties can actually change during tracking without subjects being aware of the changes (Bahrami 2003; Pylyshyn 2007). Thus, FINSTs individuate and track visual objects but do not deliver descriptions of the properties of the objects that they index.

Of course, FINSTs make up only one component of Pylyshyn's theory. Other aspects of this theory are representational because once FINSTs are used to access visual objects, the features made available via inspection are then used to

create mental representations of the visual world. However, the fact that mechanisms that are consistent with embodied perception define an important part of early visual processing in this hybrid theory indicates embodied perception's growing influence in the discipline.

<sup>2</sup>Amity Institute of Neuropsychology and Neurosciences (AINN), Amity University, Noida, UP, India

<sup>3</sup>Endocrinology and Metabolism Division, National Institute of Nutrition (NIN), ICMR, Tarnaka, Hyderabad, India

## Synonyms

Fertilized egg; Unborn child/baby

## Definition

Embryo is the earliest prenatal phase of development *in utero* between the fertilized egg and the end of eighth week of gestation (in human), after which it is termed as fetus.

## Introduction

In the simplest form, embryo can be defined as a collection of cells generated from the fertilized ovum after implantation in the uterine wall till the eighth week of gestation (in human). Therefore, embryo defines the phase of development between fertilized ovum and fetus. It is the derivative of zygote that is intended to become the offspring (fully developed both anatomically and physiologically and able to survive as a separate organism) (Gould 1977).

Generally, embryo as a term for vertebrates correlates differently for different animals. It can belong to the developmental stage anytime before birth/hatching or till it becomes fetus or until it structurally resembles the adult form (Harrison 1969, 1988). Most rapid growth is

observed during the embryonic stage in most of the animals.

## Embryogenesis

The study of the development of an embryo is called embryology. When a sperm of the male fertilizes an egg cell (ovum) in the female, it forms a zygote containing DNA from both the parents (Gilbert 2010). The zygote then divides mitotically to produce a multicellular organism, which is known as embryo. This transition from zygote to embryo occurs through explicit discernible stages of blastula, gastrula, and organogenesis. A fluid filled cavity (blastocoel) is formed which is surrounded by a spherical sheet of cells (blastomeres) in the blastula stage. During gastrulation stage, single layered blastula is reorganized into a multilayered gastrula forming distinguishable germ layers (ectoderm, mesoderm, and endoderm; as in triploblastic organisms) (Stern 2004). After gastrulation, various molecular interactions between the germ layers result in differentiation of organ-specific cell types and this process is known as organogenesis. Different tissues are formed during process like myogenesis (muscle), neurogenesis (brain, spinal cord, and peripheral nerves), etc. In this way, the embryo is formed (Gilbert 2010) (Fig.1).

## Terminology for Embryo on the Basis of Appearance of Somites

1. **Presomite embryo:** When the embryo is at any stage before the appearance of the first somite, it is known as presomite embryo.
2. **Previllous embryo:** It is the embryo till the placental chorionic villi grow.
3. **Somite embryo:** The embryo between the appearance of the first and the last somites is called somite embryo.

## Stages of Human Embryonic Development

The human embryonic period (*i.e.*, the first 8 weeks of gestation, postovulation) is divided into 23 distinctive developmental steps, known as Carnegie stages (Hill 2017). It is named after Carnegie Institute of Washington, USA, which collected and classified embryos. These stages of the embryo are distinguished from each other on the basis of external or internal morphological development, independent of size or age.

The Carnegie stages can be grouped into different weeks. First week has Carnegie stages 1–4, whereas week 2 has stages 5 and 6. Similarly third week has 7–9, fourth week has 10–13, fifth week has 14 and 15, sixth week as 16 and 17, seventh

**Embryo, Fig. 1** Embryogenesis. An embryo develops from the zygote and reaches fetus stage before becoming a fully grown up offspring which is ready to take birth. This

includes the most complex physiological and morphological changes in an organism

week has 18 and 19, and finally the remaining stages 20–23 come under eighth week (Hill 2017).

On day 1 of first week (stage 1), the size of fertilized oocyte or zygote is between 0.1–0.15 mm, which increases up to 0.2 mm by the end of 15th day. On second and third day (stage 2), there is reduction in cytoplasmic volume forming morula, after which blastocyst is formed. There is a loss of zona pellucida and the blastocyst is found free till day 5 (stage 3). During days 5–6 (stage 4), the blastocyst gets attached and implantation occurs between days 7 and 12 (stage 5). This is followed by the appearance of extra embryonic mesoderm, primitive streak, and gastrulation between days 13 and 15 (stage 6). Gastrulation continues and notochordal process appears in week 3 between days 15–17 (stage 7) and the size of the embryo at this stage is around 0.4 mm. The embryo grows rapidly to size of 1.0–1.5 mm between days 17 and 19 (stage 8) when the primitive pit is formed and notochordal canal appears. This growth is followed by somitogenesis, where different somites are formed as follows: (a) somite 1–3, neural folds, cardiac primordium, and head fold are formed (embryonic size = 1.5–2.5 mm, stage 9), (b) somite 4–12 are formed and neural fold fuses (embryonic size = 2–3.5 mm, stage 10), (c) somite 13–20 are formed and rostral neuropore closes (embryonic size = 2.5–4.5 mm, stage 11), (d) somite 21–29 are formed and caudal neuropore closes (embryonic size = 3–5 mm, stage 12), and (e) somite 30 is formed with appearance of leg buds, lens placode, and pharyngeal arches (embryonic size = 4–6 mm, stage 13). By now the embryo reaches a size of 5–7 mm at stage 14 in the week 5 where between days 31 and 35, lens pit and optic cups are formed. Then in stage 15 between days 35 and 38, lens vesicle, nasal pit, and hand plate are formed with embryonic size of 7–9 mm and then the nasal pits move ventrally in the stage 16 (week 6, days 37–42, size 8–11 mm) along with the development of auricular hillocks and foot plate. Between days 42 and 44 at the stage 17, embryonic size becomes 11–14 mm and finger rays can be clearly seen. At stage 18, ossification starts during days 44–48 with size reaching 13–17 mm. Straightening of trunk can be seen at the stage 19 (days 48–51, size

16–18 mm) and then during 51–53 days (in week 8, size 18–22 mm) the upper limbs become longer and get bent at the elbows. At stage 21, during days 53–54 the embryonic size is 22–24 mm and the hands and feet turn inwardly. Between days 54 and 56 (stage 22), overall size becomes 23–28 mm, and eyelids and external ears can be clearly observed. Finally at stage 23, between days 56 and 60 the embryo reaches a size of 27–31 mm and rounded head, body, and limbs are observed. After this stage, the embryo turns into a fetus, which grows till birth that occurs in around 37 weeks (Hill 2017).

## Conclusion

Embryo is the developmental stage between the zygote and fetus where highest growth and differentiation (cellular and molecular) occurs.

Biology, University of Torino, Torino, Italy

Emotional contagion is the process leading to the emotional state matching between two interacting subjects: the individual experiencing a particular emotional state and the observer. Emotional contagion is considered a basic building block of empathy and makes individuals able to share emotions. Empathy, in its most complex definition, is a phenomenon that implies the ability to perceive and interpret what another person is feeling and understand their needs (de Waal and Preston 2017).

Emotional contagion is so influential and pervasive in driving the feelings of people (fear, sadness, joy, surprise, etc.) that it has become of interest not only to the academic disciplines

(anthropology, psychology, sociology, neuroscience, ethology, etc.) but also to the working, marketing, entertainment, and political domains (Decety 2012). In the working context, emotional contagion can significantly influence individual attitudes and group processes. For instance, positive emotional contagion between group members was found to improve cooperation, decrease conflict, and increase perceived task performance at work (Barsade 2002). Advertisement, politicians, and film or theatre scenes often fake emotional sharing to enhance involvement, increase motivation, and boost audience approval and support. For example, when watching scenes involving laughter or cry, we are aware that the actors are emoting (cognitive consciousness) and still we are often infected by faked feelings and internally reproduce real emotions. This reveals that our emotional responses are unconscious and unstoppable, and cognition has limited control over our immediate reactions.

The reason why emotional contagion has been naturally selected over the course of evolution is under debate. The most accepted explanation that accounts for the evolution of emotional contagion is social living. Humans live completely nestled in an emotional network that makes us socially interdependent beings. Obviously, in this social world, we are not alone and also other animal species are able to experience and express emotions. Unveiling emotions is essential to communicate with conspecifics and synchronize many social activities. A large bulk of research has been recently devoted to understand how emotional contagion comes into play, how humans and other animals get to share emotions, and what are the proximate and ultimate causes of this phenomenon (de Waal and Preston 2017).

## Rapid and Spontaneous Mimicry

One of the most fertile fields of research is the facial and bodily motor expression of emotions, including how human and nonhuman animals are able to perceive the emotions of others by mimicking the same motor pattern that makes such emotion manifest. Emotional contagion

and resonance occur when an observer pre-consciously activates shared emotional representations during the perception of an action or of a facial expression. This activation response, known as perception-action coupling, is a basic requirement of empathy because it leads individuals to automatically experience others' affective states (Christov-Moore et al. 2014; de Waal and Preston 2017). Literature indicates that the ability to emotionally empathize involves the mirror neuron system and different brain areas (the inferior frontal gyrus (IFG) especially, but also the inferior parietal lobe (IPL); the anterior cingulate cortex (ACC); and the anterior insula (AI); Shamay-Tsoory 2011).

One of the mechanisms that informs emotional contagion is rapid and spontaneous mimicry, the fast (less than 1 s), unconscious, and unintentional imitation of behavior shown by two interacting partners leading to motor facial and bodily resonance (Hess and Fischer 2013).

According to some definitions (e.g., Whiten et al. 2009), true imitation requires that the observer both recognizes the goal of the demonstrator and reaches that goal by exactly copying the observed sequence of actions. Mimicry, on the other hand, does not involve any recognition of the goal (for review: Palagi and Scopa 2017). The process that links mimicry and emotional contagion involves two steps. Firstly, the perception of others' expressive behavior automatically induces the observer to mirror such behavior. Secondly, the mimicry of others' behavior can induce the observer to share the emotional state underpinning such behavior (Dezecache et al. 2015). It is in order to specify that rapid mimicry and emotional contagion, although possibly interacting, are distinct concepts, because each can occur independently (Nakahashi and Ohtsuki 2015; Palagi et al. 2015). This is, for example, the case of consolation, explained better below.

From a functional point of view, mimicry regulates dyadic relations and favors the formation of strong, enduring social bonds, which in turn enhance reproductive success. Mimicry is an honest signal of affiliation whose perception informs the demonstrators on the ongoing emotional synchronization (Kavanagh and Winkielman 2016; Niedenthal et al. 2010). This emotional sharing

makes individuals more inclined to interact in a positive way, which opens the way to strong long-term social bonds. Therefore, the value of mimicry relies on the fact that it is a true signal of emotional contagion (Kavanagh and Winkielman 2016).

Considering the importance that mimicry plays in sharing emotions and regulating social interactions, it is not surprising that this phenomenon is more widespread in mammals than previously thought. The presence of emotional contagion has also been demonstrated in birds. In an elegant playback experiment, Schwing et al. (2017) showed that New Zealand parrots (*Nestor notabilis*) are emotionally infected by the playful vocalizations of conspecifics. During the administration of the play calls, the authors recorded an increase of play frequency and duration in the receivers that started to play with nonplaying birds, thus demonstrating that play vocalizations can act as positive emotional contagion.

In the last decades, many researchers have become increasingly aware that the only possibility to understand even the most complex forms of human empathy is to look at other branches on the evolutionary tree. As a result of this new interest, some convincing data emerged on similar phenomena in nonhuman species. In primate and nonprimate species, rapid mimicry is a good regulator of social interactions and reliable predictor of emotional closeness.

Play provides researchers with the opportunity to investigate the relationship between rapid mimicry and emotional contagion because play is punctuated by a unique, behaviorally specific facial expression, the relaxed open mouth display (ROM), which is unequivocally associated to a positive emotion. The possibility to use ROM, homologous to human laughter, is particularly important in the study of nonhuman animals in which deciphering the emotional state is not trivial. In geladas (*Theropithecus gelada*), the presence of rapid facial mimicry involving ROM allowed the players to engage in longer play sessions by enhancing emotional synchrony (Mancini et al. 2013a, b). A similar phenomenon was found also in chimpanzees (*Pan troglodytes*), lowland gorillas (*Gorilla gorilla gorilla*; Palagi

et al., submitted), and domestic dogs (*Canis lupus familiaris*; Palagi et al. 2015). Interestingly, rapid facial mimicry was found in the tolerant Tonkean macaque but not in the despotic Japanese macaque (*Macaca fuscata*) (Scopa and Palagi 2016). Hence, rapid mimicry appears to be sensitive to the relationships established via emotional bonding rather than via dominance power. In geladas, it was also observed that in the first months of life, the highest levels of rapid facial mimicry were present between mothers and their offspring (Mancini et al. 2013a), thus supporting the empathic gradient hypothesis, which predicts that the emotional involvement is maximum between closely bonded subjects (de Waal and Preston 2017).

Facial mimicry is a visually-based form of emotional contagion. Nevertheless, other sensory cues can vehicle emotions from a subject to another. In humans, it was demonstrated that listeners were able to discriminate whether American English people laughing together (collaughter) were friends or not with one another. The listeners, who belonged to 24 different societies from all over the world, were capable to do so just by hearing a short audio-record without receiving any visual indication. The level of laughter contagion in the listener was highest when hearing friends laughing. Hence, vocal mimicry represents a valuable communicative signal of relationship quality, independent of the sociocultural background. While discussing their results, the authors pointed out that the emergence of articulate language did not erase our ability to use unconscious facial/vocal signals of affiliation (Bryant et al. 2016). They posited that during the evolution of our species, those individuals who were able to decode nonverbal communicative exchange between others and understand their level of social bonding, probably obtained advantages in terms of fitness.

## Yawn Contagion

In 1872, Darwin defined yawning as a wide gaping of the mouth, until the acme is reached, followed by a passive closure of the jaws, with all phases accompanied by respiratory

components. Yawning has often been considered a *stereotyped action pattern* due to its consistency in duration, morphology, and frequency (*Homo sapiens*, Provine 2005). The yawning motor pattern is an ancient (plesiomorphic) facial display that can be unambiguously recognized (Baenninger 1997). Yawning can be spontaneous or triggered by another yawn. In particular, yawn contagion occurs when someone yawns in response to someone else's yawn (Provine 2005). Even though the way to exactly quantify the phenomenon is under debate, yawn contagion has been demonstrated in human and nonhuman primates and even in dogs and wolves (de Waal and Preston 2017). Similarly to mimicry, contagious yawning is a preconscious response and it is therefore scarcely affected by cognitive biases (Provine 2005). As mimicry, it relies upon the perception-action mechanism involving the mirror neuron system (de Waal and Preston 2017) and recruits different neuronal networks involved in empathic processing, including the inferior frontal gyrus (IFG) and other mirror neuron areas (Arnott et al. 2009; Cooper et al. 2012; Haker et al. 2013; Nahab et al. 2009). Yawn contagion is biased by the same variables that affect emotional contagion, the basic layer of empathy (de Waal and Preston 2017). As empathy, yawn contagion increases with age starting at 3–5 years when the ability to identify others' emotions is being acquired and declines with old age when empathic abilities also decline (Hoogenhout et al. 2013; Millen and Anderson 2011; Saxe et al. 2004).

Yawn contagion is present between strangers in both humans and bonobos (Norscia and Palagi 2011; Tan et al. 2017) and this is in line with findings demonstrating that the subjects of both species can provide help to unfamiliar individuals and not just to familiar ones (Tan and Hare 2013; Raihani and Bshary 2015). Nevertheless, yawn contagion follows the empathic trend because it is more frequently observed between familiar than between unfamiliar individuals in both humans (Norscia and Palagi 2011) and non-human primates (monkeys, Palagi et al. 2009; apes, Demuru and Palagi 2012). A study considering both humans and bonobos showed that familiarity is the factor that most influence the likelihood of observing yawn contagion, being

this factor even more salient than the biological species the individuals belong to (Palagi et al. 2014b). In humans, within the population susceptible to yawn contagion, women respond more frequently to others' yawns compared to men (Chan and Tseng 2017; Norscia et al. 2016). Consistently, psychological and neurobiological studies converge in indicating that women are more responsive to others' emotions than men, possibly because women are hardwired for maternity and parental care (for a review, see Norscia et al. 2016).

Although the issue is still a matter of lively discussion within the scientific community, the above reasons suggest that yawning after perceiving others' yawns is driven by emotional contagion.

## Consolation

In humans, the act of providing comfort via spontaneous affiliation offered to a distressed subject is widely accepted as a crucial behavior that can reveal the empathic potential of individuals. In nonhuman primates, third-party affiliation is behaviorally described as the first affiliative contact occurring between the recipient of an aggression (namely, the victim) and a bystander not involved in the aggression (de Waal and van Roosmalen 1979). More generally, consolation is a reassurance behavior directed at a distressed subject and it is driven by the emotional contagion experienced by the consoler in response to victim's anxiety. In particular, consolation is probably triggered by the transfer of negative affect from the victim to the observer. Consolation has been found not only in primates (including apes and tolerant monkey species), but also in canines, elephants, rodents, and corvids (de Waal and Preston 2017).

The witness of a fight can affiliate with the victim either spontaneously or upon the request of the victim. The comparison between these two forms of third-party affiliation can reveal why only the spontaneous consolatory behavior is driven by emotional contagion. In bonobos, a long-term study showed that both spontaneous

and solicited affiliation led to increased protection of the victim against further aggression. However, the victims experienced anxiety reduction only after receiving spontaneous affiliation. Hence, the improved emotional state in the victim was not the mere by-product of risk reduction but the consequence of the perceived the genuine emotional involvement of the consoler. The spontaneous comforting gesture relying on the motivational independence of the consoler (de Waal and Preston 2017) may hold a greater significance to the victim as it was initiated by the consoler who, most frequently, was an individual the victim shared a good relationship with.

As it occurs with rapid mimicry, also consolation seems to be affected by the levels of social tolerance between subjects. In the same group of *Macaca tonkeana* in which facial mimicry had been found, consolation was present. In the group of *Macaca fuscata*, the absence of facial mimicry was associated with the lack of consolation (Palagi et al. 2014a; Scopa and Palagi 2016). This is consistent with the strict linkage that both phenomena have with emotional contagion, and with the influence that social tolerance has on it.

In summary, emotional contagion is based on the ability to internally reproduce the feelings of others. It can be expressed through behavioral patterns, such as mimicry, yawn contagion, and consolation, provided that the social context allows their expression. To date, no case study has been able to disentangle social modulation and emotional contagion.

Because it is the basic building block of complex forms of empathy, such as perspective taking and targeted helping, emotional contagion must be taken into account when approaching the study of such forms of empathy whatever the studied species may be.

## Empathy

Garet P. Lahvis  
Oregon Health and Science University, Portland,  
OR, USA

## Introduction and Definition

Many of us experience empathy, yet this feeling eludes the direct measurement often required for scientific understanding. Empathy cannot be quantified by a functional MRI scan of the brain, yet we can use relatively simple language to describe it. The purpose of this entry is to delve into the various features of empathy and how we can use scientific approaches to infer its properties. For the most part, empathy will be discussed in the context of experiments with non-human animals. While so doing, we will explore the differences between motivation and behavior, affect and cognition, and empathy and compassion.

The modern concept of empathy originated in the late 1700s, introduced as the German word *Einfühlung* and referring to the human extension of oneself into the “consciousness” of the natural environment. *Einfühlung* was also used to describe the viewer’s active participation in a work of art, of “feeling into” the perceived object (Nowak 2011). In 1909, the term was adopted into the English language as “empathy” and rapidly embraced by psychologists.

Empathy is a subjective experience, not a behavior. Subjective experiences include feelings (affective experiences), thoughts (cognitive experiences), and sensory perceptions (what we see, hear, smell, feel, or taste). At its core, empathy refers to the feelings engendered by witnessing the situation of another individual. For instance, imagine that you are a bystander who witnesses a child falling off a moving bicycle and skinning her knee on a concrete driveway. Seeing the fall, you might feel a wincing sensation. When I imagine her fall, I feel a sharp tingling on the inside of my arms. The sensation might vary from person to person, even from time to time, but the sensation would likely be direct and immediate and evoke an emotional response. Your affective experience might be even more salient if you had also skinned your knee against concrete.

In other instances, empathy might include cognitive function, such as the experience you might feel upon learning of the aftermath of the 1890 Massacre of Wounded Knee. If I describe to you the strewn dead bodies of native American women and children who just hours earlier were waking up to a peaceful cold winter morning, the scene might arouse in you a feeling of loss or anger at the cavalry who massacred them. You might imagine the din of report and smoke from the cavalry guns and the screams of children in a massacre that occurred well over a century ago. You might never have seen an actual slain human body or a native village. Your cognitive process – of imagining from my description of a scene of strewn bodies – might evoke in your emotions something akin to what the few surviving natives might have felt when they looked over their destroyed village on that cold morning on the American plains.

A modern definition of empathy encompasses both affective and cognitive contributions but asserts that affective experience resides at empathy's core: "the generation of an affective state more appropriate to the situation of another compared to one's own" (Hoffman 1975; Preston and de Waal 2002). Empathy is adopting the feelings of another: their fear, joy, pain, anxiety, appreciation, or disdain.

In current popular usage, "empathy" has often been jumbled with feelings of compassion or with behaviors associated with compassion, such as helpful or altruistic acts or displays of sorrow for a victim. Compassion is a feeling related to helping behavior that includes empathy or an awareness of another individual's distress, *but compassion also includes a desire to alleviate that distress*. Indeed, helping behavior can arise from compassionate feelings. For the sake of scientific inquiry and the ongoing need for precision in language, strict boundaries on the term empathy can help us to understand its evolution and neurobiology. So again, empathy is not compassion or a compassionate act because it does not require a desire to alleviate the distress in others.

## Empathy and Affective States

A close relationship exists between subjective experience and behavior, so these terms are often confused. In our daily lives, we commonly infer one another's motivations from behaviors. Often times, different people make different inferences. A woman might shade her eyes with sunglasses. I might infer that the sunlight hurts her eyes. You might infer that she'd like to hide her eyes. Someone else might think she's showing off her new sunglasses.

We also infer subjective experiences from language. We commonly assume that if we use identical words to describe our experiences, we share identical experiences. Bertrand Russell argues that words can evoke unreliable inferences to subjective experience. For instance, two people might look at the same object and use the same word to describe its color, yet neither one of them can know whether they both experience the same

color (Russell 1912). We might both look at the same ripe apple, and you might see it as crimson while I might see it as magenta, yet we both would say that we see the apple as "red." I might see the apple as what looks like purple to you – yet by calling it red – we still would be ignorant to the discrepancy between our experiences.

How can we observe a behavior and infer subjective experience? To answer this question, it is helpful to consider the seminal contributions of Theodore C. Schneirla regarding the psychology of motivated behavior (Schneirla 1959). An individual animal might be motivated to move toward or away from a setting, an object, or another individual. How can we infer whether an approaching behavior indicates that the individual is seeking a certain experience? Likewise, how can we infer that a withdrawing behavior indicates an intention to avoid a particular setting, object, or individual? I might seek an orange sphere in my environment with a particular weight, texture, and fragrance because I associate it with the rewarding experience of peeling its rind and eating its wedges. Likewise, we both might withdraw from a situation where we expect an aversive experience, like the sting felt when we touch the nettles of a certain green plant.

Our affective experiences of seeking and avoidance are the proximal mechanisms that often underlie our approach and withdrawal behaviors. But we must be careful. Not all approach and withdrawal behaviors result from psychological experiences. For instance, if we watch an amoeba move across a petri dish, we cannot infer that the single-celled organism *wishes* to cross the plate. An amoeba lacks a central nervous system.

The critical scientific problem with empathy is that while we can understand what empathy is and how it emerges as a feeling, we are asking about a subjective feeling experienced by one individual that is responsive to the subjective experience of another – and all this seems remarkably inferential and outside the realm of scientific inquiry.

To tackle this problem, we must return to what we know. Empathy occurs in the context of a social interaction, even if that interaction is with a historical or fictional character. In these social interactions, behaviors signal the emotions of

others in the words spoken and their intonations and in facial expressions and gestures. These emotions can be intentionally directed toward one another or not be intentional at all. For instance, when an individual animal vocalizes, emotions can moderate the acoustic parameters of the vocalization, such as loudness and pitch (Scherer 1986). Emotions can be conveyed by vocal utterances that may not be intended for communication, such as a laugh, a sigh, or a grunt. Visual cues can also convey emotions, often as body movements, such as the redirection of eye gaze, an extra bounce in a step, the hair that stands on end along the backbone of a frightened dog, or the slow slumped pace of a person walking home from work. In a social interaction, we attend to eye movements, facial expressions, hand gestures, and gait to gain some clue to the internal experiences of the individual we interact with. Intended or involuntarily, each behavioral expression of an emotion is then either correctly or incorrectly perceived and can pivot the direction of a social encounter.

We consider empathy as an affective experience. Although we commonly use the word “emotion” interchangeably with “affective experience,” emotions are one of several affective experiences that occur during a human or non-human social encounter. Others include moods, interpersonal stances, and attitudes. Some occur in an instant. Others endure over much longer periods. Affective experiences influence what each participant of a social interaction anticipates when meeting another individual and what they might perceive correctly or incorrectly in another’s motives and emotions (Scherer 2003). An *emotion* is a relatively brief, in-the-moment response to an external or internal stimulus that is valued as being of major significance (anger, sadness, joy, fear, desperation). A *mood* is a more diffuse but still labile affective state, experienced as a change in subjective feeling, of low intensity but relatively long duration, often without apparent cause (cheerful, gloomy, irritable). An *interpersonal stance* is a feeling associated with another specific individual that colors the interpersonal exchange in that situation (cold, warm, supportive, contemptuous). We might consider whether dominant-subordinate relationships are

interpersonal stances. An *attitude* is more enduring than an interpersonal stance: affectively colored beliefs, references, and predispositions toward objects or persons (liking, loving, hating, desiring). We might ask whether the male-female pair bonds of a variety of species are behavioral expressions of attitude. How pinyon jays make transitive inferences about dominance hierarchies by watching the hierarchical interactions of others (Bond et al. 2004) might reflect an adjustment of attitude. *Personality traits* are not affective experiences, per se, but they are emotionally laden, stable dispositions and behavioral tendencies of an individual (nervous, anxious, hostile, jealous) that have been demonstrated in studies of mice (Caramaschi et al. 2008). A personality trait might dictate how a social encounter is experienced or might explain why certain affective experiences are predictably experienced in particular situations.

While affective states are not directly measurable, we can use these terms to dissociate their various attributes across a range of possible social encounters. With this framework of affective experiences transpiring during a social encounter, empathy might be responsive to changes in emotions and moods. The behaviors expressed during a social encounter are moderated in part by these emotions and moods and correctly or incorrectly perceived through the context of interpersonal stance, attitude, and personality trait. With this background, we can now turn our attention toward experimental techniques that allow us to infer a subjective experience of empathy.

## Experimental Considerations

How can we infer that an individual has acquired *an affective state more appropriate to the situation of another compared to one’s own*? If we are inquiring about humans, we might ask how a person feels after witnessing someone else experience a change in mood or emotion. But, as mentioned earlier, language has its shortcomings. Words are labels or tags we use to convey our emotions, but it is impossible to know whether one person’s feelings of anger or sadness match

those of another person who is describing feelings with the same words.

How can we infer an affective experience of empathy? One approach used by scientists to gain inferences about empathy in rodents is to use a modification of a tool employed in many learning experiments called “fear conditioning.” The first step in these experiments involves “conditioning,” whereby the rodent learns that when it experiences a particular environmental cue or context, it will experience an aversive stimulus. The environmental cue might be a tone or a small light that turns on and off. An environmental context might include different visual patterns on the walls of the chamber where the rodent is placed. The aversive stimulus might be an electrical shock or an air puff.

When a laboratory mouse experiences an electrical shock, it vocalizes at a frequency that is audible to the human ear and sounds like a squeak. These vocalizations do not resemble the ultrasonic vocalizations emitted for communication (Chen et al. 2009) or the precise overtone frequency modulations used for alarm calls by other rodent species (Kiriazis and Slobodchikoff 2006). They are harsh and audible. When a laboratory rat is administered a shock, it vocalizes at a frequency of approximately 22 kHz (Atsak et al. 2011), which is above the frequency audible to the human ear. These 22 kHz calls are often emitted by rats placed under aversive conditions.

During the conditioning phase, the rodent is exposed to an aversive experience, such as a shock (what scientists call an unconditioned stimulus), administered in conjunction with exposure to an otherwise innocuous cue or context (conditioned stimulus). For instance, in *context-dependent* fear conditioning, a rodent might be placed inside a chamber with horizontal stripes on the walls where it does not receive any shock. Placement of the rodent in this context is alternated with placement in a different chamber with vertical stripes on the walls where the rodent is delivered an electrical shock. With repeated exposures to both chambers, one with shock and one without, the rodent begins to express freezing behavior inside the chamber where it is administered the shock. With each successive pairing of the chamber with the

shock, the rodent’s freezing behavior becomes more prolonged and more frequent. In the control condition, in the chamber with the horizontal bars, the rodent does not freeze express an increased level of freezing behavior. In this example of *context-dependent* fear conditioning, the rodent learns that the patterns of the stripes on the walls of the chamber are predictive of the presence or absence of an impending electrical shock.

In *cue-dependent* fear conditioning experiments, the rodent is exposed to a temporal cue, such as a tone, that is paired with the aversive experience. In the testing that follows fear conditioning, the rodent is exposed to the tone (the conditioned stimulus) without the associated aversive experience of the shock (the unconditioned stimulus), and we measure the frequency and duration of freezing behavior in response to the tone.

Freezing behavior appears as a nearly motionless trembling in place and may be the expression of fear in anticipation of an imminent shock. We cannot infer with absolute scientific certainty that freezing behavior is a manifestation of fear. However, physiological, anatomical, and ethological responses of rodents to fear conditioning bear a strong resemblance to correlates of human fear, suggesting that freezing behavior manifests this highly salient affective experience.

To test for empathy, this experimental paradigm is slightly modified. The test subject is no longer the rodent undergoing fear conditioning but a different rodent that witnesses the rodent that undergoes fear conditioning. In many cases, empathy experiments use cue-dependent fear conditioning. The cue is often a tone. In this experimental model, the rodent that is administered the electrical shock is called the “object” or the “demonstrator.” The rodent that witnesses the conditioning is the test subject and is often called the “observer” or “witness.” While the demonstrator undergoes fear conditioning, the witness resides inside an adjacent chamber where it can hear the tone and the demonstrator’s vocalizations in response to shock.

In our experiments, both the demonstrator and the witness are subjected to a 30-s tone. For the demonstrator, the tone co-terminates with a 2-s electrical shock. During this 2-s period, the

demonstrator vocalizes in response to the shock. For the witness, the tone co-terminates with this 2-s vocalization emitted by the demonstrator. Following the 30-s tone, both the demonstrator and witness mice experience 90 seconds of silence. The tone is then played again and co-terminates with a shock. Then there is silence. With repeated tone-shock pairings, demonstrator mice inside the shock chamber freeze when they hear the tone. After conditioning, the test subjects that witnessed the demonstrators undergo conditioning are then placed inside the shock chamber. If they freeze when they hear the tone, we can infer that they have learned from the demonstrator mice that the tone predicts an aversive experience (Chen et al. 2009). We know from playback studies that the vocalizations emitted by demonstrator mice during the shock are sufficient to generate a freezing response by witness mice to the tone once they are placed inside the shock chamber (Chen et al. 2009).

In these “vicarious” fear conditioning experiments, researchers typically administer to the test subject (the witness) a single exposure to the aversive experience (Chen et al. 2009; Atsak et al. 2011; Sanders et al. 2013; but see Jeon et al. (2010). For example, in the experiments described above, prior to the conditioning of the demonstrator, the witness is administered an aversive shock. Critically, *the shock is not co-administered with the cue or context*. This pre-treatment is thought to give the witness a sense of the adversity of the shock experience. Interestingly, when investigators temporarily deafen the witness before administering the aversive stimulus, so that it cannot hear its own vocalization in response to the shock, the witness subsequently fails to learn from the vocalizations of others that the tone predicts the shock (Jeon et al. 2010). Like rodents, humans who have experienced a specific adverse experience in the past are more likely to feel empathy for another individual undergoing a similar trial (Batson et al. 1996; Eklund et al. 2009; Preis and Kroener-Herwig 2012).

What should be highlighted here is that animal researchers who use ethologically relevant stimuli, such as threats relevant to the evolution of a mouse, may not require that the subject have

direct experience with the aversive stimulus. For instance, mice can learn from others to bury themselves in cage bedding to escape from biting flies after they observe a single successful escape (Kavaliers et al. 2001).

It is also important to recognize that “vicarious” fear learning is only one kind of “observational” learning. In the example above, the test rodent learns to become fearful of a stimulus that another rodent finds painful, or at least unsettling. Vicarious fear conditioning experiments can be used to identify the biological correlates of empathy inside the brain. Indeed, the brain activity patterns of rodents that witness demonstrators bear aversive conditions show a remarkable resemblance to brain activity patterns of humans under similar conditions. For instance, rodent and human subjects that witness a pain response in demonstrators express increased circuit activity in the anterior cingulate cortex and the amygdala (Jeon et al. 2010; Kim et al. 2014; Singer et al. 2004, 2006).

Some forms of observational learning may not require empathy, such as some behavioral tasks that are motivated by access to a food item. In this case, observational learning requires that the test subject have the ability to learn the sequence of behavioral movements necessary to obtain the reward. The subjects are evaluated for their ability to perform a task after witnessing demonstrators perform a set of behavioral movements to gain access to the reward.

In empathy experiments that use fear conditioning, test subjects are not learning to reproduce the mechanics of a behavior. Further, we find that nuclei of the amygdala are activated during the freezing responses in these experiments and since these activities can correlate with fearful experiences, these biological findings support the inference that the learned freezing responses of the test subjects are behavioral expressions of fear.

A different measure of socially related behavior allows experimenters to assess “contagion,” a behavior that may, at least in some cases, involve empathy. Contagion might include adults yawning or babies crying in unison. In a classic experiment of contagion, mice are brought together after they have been injected with different

concentrations of irritants, either into the peritoneum (acetic acid) or into the paw (formalin). When these mice are separated, they show differences in their levels of writhing and paw licking behaviors proportional to the concentrations of irritant injected into their peritoneum or paw. However, when mice are injected with different concentrations of irritant and placed next to one another, their behavioral responses converge such that differences in their writhing or paw licking behaviors diminish (see Langford et al. 2006). This convergence of behaviors may suggest empathy, but we cannot infer the affective experience from the behavior because the test does not separate the social stimulus from the behavioral response.

We can infer empathy from conditioning experiments because the tested behavior is an expression of retained affective experience. The witness learns to associate an otherwise innocuous environmental cue or context with pain by witnessing another rodent undergo the painful experience. The rodent witnessing its conspecific undergo conditioning embodies this affective experience and retains it through subsequent testing when it also freezes in response to the tone. Since the test phase occurs at a separate time and place from the conditioning phase, we are measuring the influence of this retained affective memory on the witness' subsequent behavior. By so doing, we capture the contribution of an affective experience, in this case, vicarious fear, on behavior.

The tests described above use adverse stimuli to measure empathy. When compared with the poverty of experience afforded to rodents living inside standard laboratory cages, repeated shocks may be a minor aversive stimulus. Biomedical research would be more ethical and, in many cases, more relevant to aspects of human health were it to provide laboratory animals with ongoing challenges that can be overcome. The home environment should include a complexity of social and non-social contexts that offers both pleasurable and aversive stimuli (Lahvis 2017a, b). Empathy should also work in both directions, serving to predict both aversive and enjoyable conditions. To better understand empathy, we

should also develop tests that measure rodent responses to pleasant vicarious affective experiences.

## Why Empathy Is Adaptive

A capacity to feel into the moods and emotions of others allows an individual to sense from others emerging dangers or rewards that are not perceived directly. And since empathy is, in part, a vicarious affective experience, it can exert a much more pronounced effect on behavioral responses than what might be perceived only by cognitive understanding. An individual fearful from what it senses in another is likely to express a robust behavioral response. For instance, it is near axiomatic that while hearing an orator speak about an injustice with an angry voice, an audience is more likely to become angry and take action than would be an audience hearing an orator outline the same injustices with a dry and indifferent voice. Likewise, we would expect that the capacity to feel into the emotions of another individual (e.g., anticipation, fear, interest) would engender high levels of arousal that are appropriate for the situation versus the modest arousal that might be evoked by cognitive discernment.

For species that rear their young, a capacity for empathy also has adaptive value for parents. It can help them to adjust their behaviors to moderate the comfort of their offspring. Similarly, empathy may help offspring learn from a parent what aspects of the environment to fear or seek. After young captive-trained prairie dogs witness an experienced adult avoid a predator, they are more likely to survive release into the wild than are their unschooled controls (Shier and Owings 2007). Social learning includes imitation, where an action is copied, and emulation, where the goal of the action is understood and the mechanics of the behavior are then reproduced after subsequent trial-and-error learning. Rodents are capable of emulation (Zentall and Galef 1988; Galef 2013) and to the extent that an observer experiences the intent of the demonstrator in emulation, empathy may be involved in social learning.

Empathy is also thought to aid in rough-and-tumble play or play fighting, a behavior that is commonly expressed by young mammals. Play fighting requires that each participant be sensitive to the moment-by-moment situation of the playmate. If a move or a bite is too vigorous or not vigorous enough, play fighting ends. Drugs that dull changes in affective experience can moderate play fighting (Vanderschuren et al. 1997), suggesting that the behavior requires a responsive affective state. Play fighting promotes normal brain development (Gordon et al. 2003; Pellis and Pellis 2007) and is believed to confer adaptive advantages that include better emotional responsiveness to unexpected events (Nunes et al. 1999; Spinka et al. 2001), familiarization with self-handicap and fair behavior (Bekoff 2004), improved social coping abilities (Van den Berg et al. 1999a), and refined abilities to respond to subtle and ambiguous social signals (Pellis et al. 2010).

### **Empathy and Altruism: The Camaraderie Effect**

One of the most provocative questions regarding wild animal behavior is why wild animals often help others even at their own personal cost. A prediction arising from the theory of evolution is that individuals that successfully compete against others for limited resources would be more likely to survive and reproduce than individuals that share resources at their own expense. A corollary to that hypothesis might be that we expect a competitive psychology among wild animals because they are singly motivated to acquire resources for themselves and their progeny.

Contrary to these predictions, scientists including Darwin have observed “biological altruism” in the wild: individuals helping others, incurring upon themselves costs to their own survival and reproduction. Also observed in the wild are the related behaviors of “cooperation,” in which individuals coordinate their behaviors to acquire resources that they would not be able to obtain by acting alone. Some altruistic behaviors are expressed by only a few species. Vampire bats

risk starvation when they regurgitate their blood meals to share them with others (Wilkinson 1984). Other altruistic behaviors are expressed among many species, such as prey species that engage in mobbing of their predators (Templeton et al. 2005; Krams et al. 2006; Graw and Manser 2007).

Behaviors expressed in the wild can be explained by either ultimate or proximal mechanisms (Tinbergen 1963). Ultimate explanations attempt to reconcile altruistic behaviors with the pressures of natural selection and include kin selection, direct and indirect reciprocity, and multilevel selection (Nowak 2006). Proximal explanations attend to their underlying mechanisms and include the psychological and biological correlates of these behaviors. Experiments that examine proximal correlates of behavior are often conducted in the laboratory.

Like wild animals, laboratory animals also express helping behaviors at the expense of their own well-being. In an experiment conducted over 50 years ago, laboratory rats were given a choice between pushing a lever to gain access to a chocolate chip and a different lever to release a nearby rat that was hanging in a harness just above a cage floor. The rats chose to push the lever relieving the distressed rat over gaining access to a food reward (Rice and Gainer 1962). In a more recent experiment, rats were presented with a similar dilemma, in this case, the opportunity to release a rat from inside an uncomfortably small container versus personal access to a food reward. Rats again choose to relieve the distressed rat and share the chocolate (Bartal et al. 2011, 2014). In yet a different experiment, rats were found to free other wet rats from a pool and share their access to a food reward (Sato et al. 2015). In this last experiment, rats that had previously been soaked themselves were more likely to help, a pattern of behavior that bears resemblance to the empathy experiments described earlier.

While a capacity for empathy might partly explain why rats help other rats, empathy is not by itself sufficient. As mentioned at the beginning of this entry, helping behavior and perhaps the underlying feeling of compassion likely include an awareness of another individual’s distress, but compassion also includes a desire to alleviate that

distress. In this regard, helping behaviors may require both empathy and a motivation to be with others (that an individual finds social encounter to be a pleasurable experience).

Like empathy, the experience of finding social interaction rewarding can be experimentally inferred from conditioning experiments. The social condition place preference (SCPP) test can be used to infer whether a rodent, such as a particular strain of mouse, seeks and derives pleasure from a social encounter (Panksepp and Lahvis 2007). Laboratory rodents typically express strong preferences for environments that have been “conditioned” by their association with access to other rodents versus environments that have been paired with social isolation (Calcagnetti and Schechter 1992; Van den Berg et al. 1999b). A rodent’s response to conditioning allows us to infer an affective state, in this case, the positive affective experience associated with access to a social reward (Panksepp 1998; Burgdorf and Panksepp 2006).

The psychological motivation for a social reward can be adaptive if it serves to catalyze opportunities for affiliative social interactions and promotes communication with others. To the extent that social motivation engenders greater attentiveness to the communication and behaviors of others, it likely enhances social learning. An individual attending to another would be more apt to learn from that conspecific. Social motivation would also promote group living, which may not be adaptive when local resources are depleted or colony parasitism is high but can be adaptive if it increases the likelihood for predator detection and improves the likelihood of identifying foraging opportunities (Hoogland 1979). Evidence that group living can be adaptive also comes from studies of animal dispersal: emigration from a colony can be associated with very high survival costs (Koopman et al. 2000; Pocock et al. 2005). As social reward brings individuals into closer proximity, this affective experience becomes adaptive too in its service to another affective experience, empathy, because it is more likely to amplify the individual’s detection and embodiment of the emotions of a conspecific, such as a threat that is not perceived directly. For individuals that derive pleasure and survival benefits

from social interactions, ostracism would be devastating.

Indeed, ostracism from colonies is well-described for adolescent mammals (see Barash 1974; Festa-Bianchet and King 1984) and has been observed among adult mammals that fail to cooperate. For instance, a wolf pack may ostracize subordinate wolves that are found mating in the pack (Peterson 1979), chimpanzees shun individuals appearing abnormal (Goodall 1986), and female rats can reject males found to have copulated with anestrus females (Galef et al. 2008).

Both social reward and empathy are heritable affective states (Panksepp and Lahvis 2007; Chen et al. 2009) and, because they may each be adaptive for survival, could thereby persist as stable population traits. The finding that captive juvenile ground squirrels express social reward suggests that positive affective experiences in a social context can be felt by wild animals (Lahvis et al. 2015), not just domesticated mice and rats that may have been selected for their affinity for social interactions by living for many generations in close quarters. Natural selection could act upon the alleles that promote the capacity for affective experiences of social reward and empathy and, as a result, increase the prevalence of interactions between these experiences in any species where social reward and empathy are heritable.

What if an individual enjoyed social reward and had a capacity for empathy? What if it could feel the affinity, indifference, or enmity of other members of the colony? Such an individual might be motivated to behave in a way that minimizes group feelings of indifference and enmity and maximizes their affinity. This combination of empathy and social reward could engender the *camaraderie effect* that, at both proximal and ultimate levels, could explain why biological altruism exists in the context of natural selection (Lahvis 2016b). Empathy of another’s stance toward one’s self, whether amicable, dispassionate, or hostile, might predict a future of ongoing social acceptance, indifference, or ostracism from the colony.

In addition to the physical risks of ostracism from a colony in the wild, the *subjective* experiences associated with social isolation might contribute to physiological detriments that

jeopardize survival and reproduction. Among humans, social rejection can increase correlates of anxiety (Blackhart et al. 2007). Among laboratory rodents, social isolation impairs brain development (Black and Greenough 1998; Champagne and Curley 2005; Wiedenmayer 2009), immune reactivity (Shanks et al. 1994; Boissy et al. 2007; Tuchscherer et al. 2010), healing from burns and wounds (Detillion et al. 2004; İşeri et al. 2010), response to ischemia (Norman et al. 2010), recovery from social defeat (Ruis et al. 1999), resiliency to metastasis (Wu et al. 2000), and competence within social hierarchies (van den Berg et al. 1999a). Subjective feelings of the hostile sentiments of other colony members would engender expectancy of social ostracism and would increase levels of anxiety. These feelings might thereby foment the physiological correlates of social isolation and compromise immune function and wound repair. By contrast, a sense of general social affinity might contribute to the physiological health of an individual in response to disease and injury. Altruistic behaviors would promote well-being in others and feelings of camaraderie from others and thus general colony-wide improvements in physiological well-being.

Taken together, the camaraderie effect could promote the expression of altruistic behavior at both proximal and ultimate levels and could serve as an essential stake in others. This stake in others is thought to be necessary for the evolution of altruistic behavior (Roberts 2005).

## Ethical Implications of Empathy

Empathy exists as a relationship between the brain and social environment, arising from the interplay between the molecules, cells, and circuitry of the brain and the social dynamics that exist outside. In this sense, empathy is an emergent property, a quantum step beyond what we can measure and manipulate in the circuitry of the brain, beyond what is genetically pre-programmed, such as knowing how to walk or how to swallow.

In this context, we must reconsider the ethics of studies of captive animals raised inside laboratory

cages. They live with few social experiences and environmental risks, adversities, and rewards, and they lack opportunities to make decisions, what they would be naturally afforded in a natural environment. Indeed, young laboratory mice that are raised without their peers lack the capacity for empathy (Panksepp and Lahvis 2016). Inside cages, research animals lack the natural substrates of brain development (Lahvis 2016a) and mental and physical activity (Lahvis 2017b). Mental activity allows an individual with a specific genetic background to adjust to his or her social and physical environment. In this sense, is it ethical to deny laboratory animals complex environments that sufficiently nourish their mental activities and offer them opportunities to engage with challenges that they can overcome? Is there possibility for scientists to give laboratory animals greater agency to make choices about who to mate with, what microenvironment to explore, or what to eat? If we fail to acknowledge the subjective experiences of laboratory animals, are we limiting our own abilities to understand human psychosocial well-being and illness?

In a broader global view, knowing that animals of other species, like our own, place value on their social interactions and can feel empathy for the conditions of others, do we have an ethical responsibility to treat them better in the context of our daily lives? We use domesticated animals for our food and comfort. We displace wild animals and clear their land for our agriculture, energy, transportation, and shelters. Should we consider how human consumption and population growth impinge on the well-being of individuals belonging to other species? Are wild animals “natural resources” or is this term no longer relevant?

In a more uplifting sense, we can live more fully with the knowledge that we are not the only sentient species on our planet. It is ironic that the concept of empathy has its roots in how humans experience their natural environments. With the discovery of empathy in other animals, we can have empathy for their situations and experiences and perhaps reestablish our own emergent psychological connection with the natural environments we live within.

## Emulation

Lydia M. Hopper

Lester E. Fisher Center for the Study and Conservation of Apes, Lincoln Park Zoo, Chicago, IL, USA

## Definition

Emulation is a form of social learning in which an observer achieves the same goal as an expert they observe, but do not copy the bodily actions of the demonstrator, as when imitating.

## Introduction

Wood (1989) provided an early definition of emulation learning when he noted that “...children not only attempt to impersonate others by imitating their actions but also try to emulate them by achieving similar ends or objectives” (p.71). Following Wood’s original description, emulation has become to be considered to encompass more meanings. For example, Byrne (1998) proposed that, in addition to Wood’s “goal directed” sense of emulation, it could also include learning the physical properties of objects; learning relationships among objects; and learning what can be done with an object. Specifically, he noted that “having seen a change of state effected, the observer knows more about the physical nature of an object: that nuts crack, that rocks are heavy and hard, that fruit peduncles are flimsy. . . [and/or that] having seen an object manipulated, the observer knows more about the structural relationships that make it up or into which it meshes: that nuts are hollow and contain food, that rocks can cover food, that lids are threaded . . . [and/or that] having seen an object used in a particular way, the observer knows that this functional use is possible for this sort of object: a stick can be used as a rake, the lid of a jar can be unscrewed, nuts can be smashed by striking them with rocks, a rod can be slid through a hole, fruit can be knocked down by swiping at it with sticks” (Byrne 1998, p. 604–605).

More recently, Whiten et al. (2009) provided definitions for three distinct forms of emulative learning: object movement reenactment, end-state emulation, and affordance learning. Affordance learning relates most closely to Byrne’s (1998) description of emulation, in which an individual learns about the physical properties of a task or elements within the environment, so they are then able to manipulate them in their own manner to reach a goal and can apply that knowledge to related tasks. End-state emulation more closely matches Wood’s (1989) original definition, in which an observer recreates the end-state of another’s actions, but through their own methods. As with body mimicry, object movement reenactment refers to an observer replicating the movements shown by a demonstrator, but in this case,

the movements of a task or tool, without the need to achieve the same goal. (Note, this entry does not expand upon it, but it is worth considering that an “end-state” is a more objective element to measure than a “goal,” as goals may be subjective, and vary by the actor, whereas end-states refer to physical changes in the environment. See Gattis 2002 for a more detailed discussion on this topic.)

## Emulation and Culture

Although emulation may involve less complex copying than imitation, it may represent a more efficient form of social learning in which the observer achieves the same goal but without “blindly” copying all the actions of a demonstrator (Horner and Whiten 2005). Additionally, although it was originally proposed that high fidelity transmission of information via teaching or imitation was required for behavioral traditions that evidenced cumulative culture, more recent experimental work with humans has revealed that emulative learning is sufficient (Caldwell et al. 2012; Zwirner and Thornton 2015, but see Morgan et al. 2015). It is also unlikely that species are either “emulators” or “imitators,” but rather that they have an arsenal of social learning mechanisms at their disposal that they can employ depending on the complexity of the task to be learned, as well as the completeness of their own personal information (Whiten et al. 2009).

## Testing for Emulation

To test for emulative learning, researchers have used a number of techniques including apparatuses that occlude the causal relationship of the demonstrator’s actions in achieving the goal (e.g., Horner and Whiten 2005); ghost control or end-state conditions (reviewed in Hopper 2010); or tests in which the method used by the demonstrator is not available to the observer when it is their turn to attempt to solve the task (e.g., Tennie et al. 2010). Such tests have been run with both humans and nonhuman animals, providing a phylogenetic

perspective on whether and when individuals are likely to emulate (Hopper 2010).

## Synonyms

Brain evolution; Corticalization

## Definition

Encephalization is an evolutionary increase in the complexity or relative size of the brain, involving a shift of function from non-cortical parts of the brain to the cortex.

## Introduction

The term encephalization has been frequently associated with the evolution of the brain and intelligence. Present explanations for encephalization derive from Marsh (1886), who described the evolution of brain size in reptiles, birds, and mammals. Marsh proposed general law of brain growth as (1) relative brain size gradually increased through geological time, (2) the increase was largely confined to the cerebral hemispheres, and (3) the increase was accompanied by an increase in the complexity of cerebral convolutions.

As per first law of Marsh, Northcutt (1984) stated that the term encephalization was used earlier to describe an increase in brain size with time. Weiskrantz (1961) defined *encephalization* as an evolutionary process in which the neocortex progressively takes over functions previously handled by the tectum and striatum (i.e., lower brain regions). This was consistent with Marsh's second law. In 1985, Jerison explained that encephalization is the increase in brain size larger than that required for control of basic body functions.

Encephalization is not a common morphological phenomenon in evolutionary biology. It is rare in “lower vertebrates” and is primarily a feature of avian and mammalian evolution. The fossil evidence suggests that encephalization is more prominent in primates (Hodos 1988).

## Understanding Encephalization Through Human Fossils

The study of brain evolution by studying endocasts of human ancestors is done under the branch of paleoanthropology known as hominin

paleoneurology. Here, the paleoneurologists have focused on analyses of cranial cavities and endocranial casts (endocasts), which were prepared from the interiors of fossilized braincases and reproduce details of external brain morphology. Sometimes, these endocasts occur naturally, but traditionally these are prepared by casting the insides of braincases with latex or some other molding material. Recent technology has made this considerably easier. For example, “virtual endocasts,” created by various 3D imaging techniques, allow researchers to reconstruct, manipulate, and measure simulated endocasts (Falk 2012).

Endocasts are facsimiles of general brain shape, but they include some details such as the location of blood vessels, cranial nerves, and cranial sutures. They can also reproduce information about the convolutions of the brain that were imprinted on the inner walls of the braincase during life. The convolutions, or folds of gray matter on the brain’s surface, consist of bulges (gyri) and the grooves (sulci) that separate them. Although hominin paleoneurologists study the sulcal patterns of endocasts, knowledge about them is limited. Hence, the analyses of brain evolution begin with the measurements of brain size which helps in better estimation of changes in size of its various parts (Hodos 1988).

## Encephalization and Brain Size

The vertebrate brain shares a common structure which appears during early stages of embryonic development as three swellings (the prosencephalon, mesencephalon, and rhombencephalon) at the rear end of neural tube. The brains of the vertebrates contain the same set of basic anatomical components and can be simply compared in terms of their size which increases with body size, but not in a simple linear proportion. In general, smaller animals tend to have larger brains, measured as a fraction of body size. For mammals, the relationship between brain volume and body mass essentially follows a power law with an exponent of about 0.75 (Armstrong 1983). This formula describes the central tendency, but every family of mammals deviates from it to some degree, in a

way that reflects in part the complexity of their behavior.

In kingdom Animalia, the brain becomes evident in phyla Platyhelminthes as an enlargement called ganglion. There are also some substantial differences in the shape of the brain which accounts for the differences between mammals and other vertebrates. These differences developed mainly in the forebrain in form of both size and shape. In nonmammalian vertebrates, the surface of the cerebrum is lined with a simple three-layered structure called the pallium, while in mammals, the pallium is a complex six-layered structure called the neocortex or isocortex. The enlargement of the cerebral cortex carries with it changes to other brain areas. The superior colliculus, which plays a major role in visual control of behavior in most vertebrates, is small in mammals, with many of its functions taken over by visual areas of the cerebral cortex. The mammalian neocerebellum is a large portion of cerebellum dedicated to supporting the cerebral cortex, which has no counterpart in other vertebrates (Falk 2012).

## EQ or Brain Size: Indicator of Intelligence

Among all the mammals, primate brain is three times larger than other mammals of comparable size, and the human brain is three times bigger than that of other primates of similar size in proportion to their body size (Faiq et al. 2013). To compare the brain size across species, encephalization quotient (EQ = brain to body mass ratio) is taken into account. Humans have EQ of 7.4–78, while that of an elephant is 1.13–2.36 and can be seen to be as low as 0.2 in opossum (Roth and Dicke 2005). The larger the brain relative to the body, the more the brain is available for heightened complex cognitive tasks, and this justifies the simplicity of EQ formulation by ranking of animals on the basis of their EQ that coincides better with observed complexity of behavior. Diet and social behavior are the prime factors on which EQ depends. Species with diets of energy-rich foods (meat, fish, fruits) have larger brains than those with relatively nutrient poor diets (plants, insects). Also, more social species

(humans, dogs, dolphins) consistently score high EQ (Lefebvre et al. 2004).

Recent research suggests that, for nonhuman primates, brain size is a better measurement of cognitive abilities than EQ. Factors such as different degrees of brain folding, which increases the surface area (and volume) of the cortex, are positively correlated to intelligence in humans other than brain-to-body mass ratio (Roth and Dicke 2005).

## Encephalization and Metabolic Disorders

The human brain is approximately nine times larger than other non-primate mammals. In the past four million years, the brain volume in genus *Homo* has increased from 400 cm<sup>3</sup> in australopithecines to 1300–1400 cm<sup>3</sup> in humans. Such large proportion of gray matter has high energy demands, which induced the instinct of overfeeding. The overfeeding causes consistently higher concentration of energy nutrients (like glucose) which leads to energy storage as fats (predisposition to obesity) and relatively higher amounts of insulin (for glucose uptake) and leptin (for fat storage). Reduction in size of gut was accompanied by reduction in size of energy-metabolizing organs (liver, pancreas, etc.) and hence an increase in metabolic stress due to work overload on these organs. Further, the brain develops resistance to excess amounts of insulin and leptin, rendering their appetite suppressing activity ineffective, thereby amplifying the food intake. Hence, assemblage of factors such as high food intake, the increased metabolic stress, and insulin resistance of the brain predisposes the human to an array of metabolic disorders such as obesity, impaired glucose homeostasis, lipid disorders, hepatic steatosis, and diabetes (Faiq et al. 2013).

## Encode

- Coding

## Encoding

John Powell Taylor  
Southern Oregon University, Ashland, OR, USA

Encoding is the process of storing information, such as personal experiences, visuospatial maps of the world, or semantic meaning. Encoding may be studied on a neuronal level or more abstract cognitive level, but both approaches reflect a

useful representation of the process by which new information is placed into mental storage.

## Neural Encoding

Encoding on a neural level involves a change in the interconnectivity between two or more neurons. Changes include establishing new connections or strengthening or weakening existing connections between neurons. Collectively, these changes are called synaptic plasticity. Long-term strengthening of neuronal connections, or long-term potentiation (LTP), is believed to be the primary mechanism underlying memory encoding. In early experiments studying LTP, researchers observed the strengthening of neuronal connections in the hippocampus of rabbits (Bliss and Lømo 1973) and the amygdala of rats (Clugnet and LeDoux 1990). Malenka and Bear (2004) argue that LTP may occur anywhere in the brain where one neuron connects to another.

## Encoding Effects

Much of the evidence on encoding derives from behavioral studies designed to determine the boundaries of the cognitive processes involved. For example, cognitive phenomena such as encoding specificity, levels of processing effects, and chunking demonstrate the expression of encoding effects using behavioral measures.

### Encoding Specificity

Encoding specificity refers to the phenomenon that the context in which something is learned is encoded along with the remembered exemplar (Tulving and Thomson 1973). For example, Godden and Baddeley (1975) observed improved memory in human participants when the encoding environment (in scuba gear on land or underwater) matched the retrieval environment. Concrete evidence of encoding specificity exists in non-humans as well, such as rats undergoing sensory preconditioning procedures with compound stimuli (Lin et al. 2013).

The implication of encoding specificity is that seemingly irrelevant stimuli may be associatively connected to relevant stimuli at the time of encoding, although the evidence for the impact of context effects on learning and memory processes is mixed (see Rosas et al. 2013 for a review). This appears to hold in animal learning as well. For example, Bouton et al. (2011) demonstrated the effects of context on rats for which button-pressing had been extinguished. The renewal of button pressing was stronger in a new context than in the one extinction occurred. Retrieval processes may be able to take advantage of this information in order to enhance the success of retrieval later, especially if the context is relevant to learning or remembering (Rosas et al. 2013).

### Levels of Processing Effect

The levels of processing effect is an encoding phenomenon in which to-be-remembered exemplars are better remembered when more effort is applied towards remembering the items ( Craik and Lockhart 1972). For example, in 1975, Craik and Tulving (1975) demonstrated the levels of processing effect when human participants judged items superficially (“Is the word in italics?” or “Does the word begin with the sound bee?”) or more deeply (“Can you meet one in the street?”). Evidence of the levels of processing effect in non-humans may be difficult to obtain. Nevertheless, there may be some evidence of a similar kind of processing in chimpanzees (Vonk and Mosteller 2013). Unlike with encoding specificity, the levels of processing effect suggests that the way to which information is attended matters to encoding processes. If attentional control influences encoding, this suggests that it may not be a purely bottom-up process.

### Chunking

A larger number of items may be more easily remembered when those items are grouped together, often in a meaningful way. This is called chunking, and it was described in the mid-twentieth century by Miller (1956). In humans, chunking may explain the extraordinary memories of expert chess players (Chase and Simon

1973) in recalling positions of pieces on a chessboard. Fountain (1990) demonstrated chunking in rats using patterned sequences of lights. He did this by training rats to track patterns of flashing lights and respond on one of six levers. Fountain reported the rats errors occurred most often at the boundaries of structural groupings in the pattern, reflecting chunking similar to that found in humans. Thus, in both humans and nonhumans, chunking effects suggest structure of the encoded material is important during the encoding process, enough that it may aid in retrieval later.

## Conclusion

Encoding is a critical part of the memory process. A failure to encode information fundamentally means that information cannot be retrieved later. For encoding to occur, some physical change is necessary at the neuronal level, demonstrated in the strengthening of connections due to long-term potentiation. The effects of encoding are also evident at the cognitive level, which demonstrate the subtleties of how information is structured after encoding, as well as the processes and information included in encoded memories. These processes are not unique to humans. Many nonhuman species demonstrate parallel encoding phenomena, which suggest a largely universal encoding process.

## Endel Tulving

Eric Legge

Department of Psychology, MacEwan University,  
Edmonton, AB, Canada

Dr. Endel Tulving (1927 –) is an experimental psychologist and neuroscientist who specializes in the study of long-term memory. Tulving is particularly well known for his introduction and development of the concept of episodic memory (Habib 2009; Roediger and Craik 1989; Tulving 1972), as well as his work related to encoding specificity (Tulving and Thompson 1973; Tulving

1974), amnesia (Habib 2009; Tulving 1985), and autoeotic consciousness (Habib 2009; Tulving 1985). Overall, Tulving is one of the most influential figures in the study of human memory, and at the time of writing, Tulving has published over 200 papers and book chapters, and his work has been cited 88,000 times (Google Scholar, Sept. 2018).

In recognition of Tulving's contribution to the study of memory, he has received numerous honors and awards. For example, Tulving has been elected to the Royal Society of London (1992) and the Canadian Medical Hall of Fame (2007) and is an Officer of the Order of Canada (2006), a Foreign member of the Royal Swedish Academy of Sciences (1991), a Foreign member of Academia Europaea (1996), a Foreign member of the Estonian Academy of Sciences (2002), a honorary member of the American Academy of Arts and Sciences (1986), a Foreign Associate of the US National Academy of Sciences (1988), and a William James Fellow of the American Psychological Society (1990) (GLS Research Society 2015; Habib 2009). Tulving has also received such awards as the Howard Crosby Warren Medal from the Society of Experimental Psychologists (1992), a Guggenheim Fellowship (1987), a Killam Prize from the Canada Council (1994), a Gold Medal Award for Lifetime Achievement from the American Psychological Foundation (1994), the McGovern Award from the American Association for the Advancement of Science (1996), and the Gairdner International Award (2005) (GLS Research Society 2015; Habib 2009).

## Biographical Details

Dr. Tulving was born in on May 26, 1927 in Estonia and immigrated to Canada in 1949 (Canadian Medical Hall of Fame 2017). Shortly thereafter, Dr. Tulving enrolled at the University of Toronto to study Psychology and graduated in 1953 at the top of his class with a BA (Honors, First Class) degree in Psychology (Roediger and Craik 1989). After this, Tulving continued to study at the University of Toronto for an

additional year, and in 1954, earned a Master of Arts degree in Psychology (Habib 2009; Roediger and Craik 1989). At the time of completing his MA, Tulving was awarded a Harvard Foundation fellowship to continue his studies as a PhD student at Harvard (Roediger and Craik 1989).

At Harvard, Tulving studied under many of the foremost scholars in psychology of the time, including E. G. Boring, E. G. Heinemann, G. A. Miller, E. B. Newman, S. S. Stevens, and B.F. Skinner (Roediger and Craik 1989). Tulving's own doctoral research focused on visual acuity and accommodation (see Tulving 1958 for a publication based on Tulving's dissertation), which he completed in 1956. After earning his PhD, Tulving returned to the University of Toronto in Canada to work as a lecturer (Habib 2009; Roediger and Craik 1989).

When Tulving returned to the University of Toronto, he found it difficult to continue his research on perception due to a lack of space, equipment, and money (Roediger and Craik 1989). As a result, he sought out other research opportunities that he could complete under such constraints. Tulving thus began his work investigating verbal learning, even though he had no previous formal training in the subject (Roediger and Craik 1989).

Tulving remained at the University of Toronto for the remainder of his career, with the exception of a short move to Yale for less than a year in 1970 (Habib 2009; Roediger and Craik 1989). Tulving officially retired from the University of Toronto in 1992 (Habib 2009) and currently holds the title of Professor Emeritus (University of Toronto, n.d.). Tulving is also currently a member of the Rotman Research Institute of Baycrest Centre for Geriatric Care in Toronto (Baycrest Health Science 2016).

## Brief Overview of Work

### Episodic Memory

In 1972, Tulving introduced the term "episodic memory" to psychology. Episodic memory was conceptualized as an information processing system of explicit (declarative) long-term memory

that was functionally distinct from semantic memory. Specifically, Tulving defined episodic memory as:

[A memory system that] receives and stores information about temporally dated episodes or events, and temporal-spatial relations among these events. A perceptual event can be stored in the episodic system solely in terms of its perceptible properties or attributes, and it is always stored in terms of its autobiographical reference to the already existing contents of the episodic memory store. (Tulving 1972, pp. 385–386)

Thus, Tulving proposed that episodic memories are memories of personal experiences that contain information related to what happened, where it happened, and when it happened (what-where-when information).

However, in 2005, Tulving revised his definition of episodic memory to emphasize the need for episodic memories to contain reference to conscious experience. This requirement thus led him to claim that “only human beings possess ‘auto-noetic’ episodic memory” (Tulving 2005, p. 4, quotations in original). Specifically, Tulving’s revised definition of episodic memory includes reference to the idea of mental time-travel in which a person travels subjectively back in time to re-experience the event as part of their recollection (Tulving 2005).

### Encoding Specificity

In 1973, Tulving and D.M. Thomson published a paper that introduced the term “encoding specificity” to the psychological literature. Tulving and Thomson (1973) stated that to-be-remembered information is encoded in conjunction with other cues that are present at the time of learning, even if one is not explicitly trying to remember these other cues. For example, if you were to learn a list of items from a piece of paper, you may also store information from the surrounding environment, such as the quiet murmur of voices nearby. Thus, when asked to recall the information for the list, the surrounding environmental cues, if still present, could act as retrieval cues to aid recall. Conversely, if they were not present, there may be nothing to cue the appropriate memory, and thus the information would not be recalled (or in other

words, the information would appear to be forgotten) (Tulving 1974).

### Amnesia and Autonoetic Consciousness

Tulving is known for working with the amnesic patient K.C. (originally identified as N.N. in his 1985 work). K.C. was an individual whom, due to a traffic accident and head wound, had profound amnesia for personal events. In particular K.C., while having reasonably intact language skills and the ability to remember semantic information, could not recall “*a single event from the past*” (Tulving 1985, p. 4), and who had difficulty planning for the future. Tulving wrote that “[K.C.’s] knowledge of his own past seems to have the same impersonal experiential quality as his knowledge of the rest of the world” (Tulving 1985, p. 4). Thus, K.C. provided Tulving with evidence that there was a separation of episodic and semantic memory that may have a physical basis in the brain. Tulving’s work with K.C. also contributed to his redefinition of episodic memory to include elements of autonoetic consciousness, or in other words, to include the ability to mentally travel in time.

## Endemism

James A. Oxley  
Independent Researcher, Measham,  
Swadlincote, UK

## Other Terms

### Precinctive

Endemism, a term originally described by botanist Augustin Pyramus de Condolle in 1820, refers to a species (animal or plant) which is unique to a distinct geographical area and thus an endemic species. It is, however, important to highlight the frequent lack of agreement on the exact meaning of this term due to its broad definition and use across biogeographical, ecological, and conservation contexts (Anderson 1994; Harrison 2013). Furthermore, the geographical scale can vary dramatically from specific location, such as islands, lake, mountains/volcanoes, and rivers. Some examples of species include the Amami Rabbit (*Pentalagus furnessi*), which is found on two Japanese islands in the Nansei archipelago (Yamada and Cervantes 2005), and the Wekiug bug (*Nysius Wekiucicola*), which is only found between 3415 and 4205 meters above sea

level on the dormant volcano, Mauna Kea, in Hawaii (Eiben and Rubinoff 2014). Other endemic species may be found only in specific countries or regions (e.g., the common Emu (*Dromaius novaehollandiae*) is endemic to Australia (Taylor et al. 1999)). Some sources stated that the geographical region is subject to a 50,000 km<sup>2</sup> threshold (also known as “local endemism”) and regions which have two or more endemic species are referred to as “areas of endemism” (Platnick 1991; Bibby et al. 1992). Endemism is caused by one or more phenomena evolutionary (e.g., formation of islands), ecological (e.g., specific climate), and human/social influences (e.g., deforestation).

Endemism can be categorized to highlight aspects about a species and the regions or areas in which it lives. This includes terms such as “Paleoendemism,” which refers to a species which had previously occupied a larger area but now lives in a smaller area to that they had previously occupied. For example, Martino Vole (*Dinaromys bogdanovi*) which is endemic to the western Balkans was previously found to have occupied a larger range during the Pleistocene period to that of which it currently does (Kryštufek and Bužan 2008). Furthermore, “Neoendemism” can be defined as a species which has recently evolved but is closely related to another species and not distributed further. The Behr’s sulphur butterfly (*Colias behrii*) only found in California in the Sierra Nevada mountain range and has been highlighted as a neoendemic species based on its limited genetic diversity and indicators of population expansion (Schoville et al. 2011). It has been noted that these forms of endemism can be indicators of different evolutionary timescales; for example, neoendemism is regarded as the start of evolutionary life whereas paleoendemism is seen toward the latter stages of evolutionary spectrum prior to extinction (Cowman et al. 2017). A further term is included for those species which are specifically endemic to specific soil types, this is known as “Edaphic endemism.” For example. The butterfly Muir’s Hairstreak (*Callophrys muiri*) is endemic to serpentine soil due to the plant on which it feeds are only

restricted to these soil types (Harrison 2013). Sources have defined further categories which includes more detailed terms, such as Morrone (2008) who refers to additional detailed terms such as autochthonous/allochthonous endemics and biogeographic relicts.

## Definition

It is a physiological functionary comprising of a network of the ductless glands in the animal body secreting a chemical messenger, called hormones, into blood circulation to carry to the target destinations, i.e., various organs and tissues/cells. Hormones act through the specific receptors expressed at the target destinations inducing signaling pathways involved in the crucial biological functions viz. growth, repair, reproduction, hunger, and survival behavior.

## Introduction

Animal body has the ductless glands as the distinct organs or cell groups inside an organ or a tissue, which exit their secretions called “hormones” in the blood circulation to carry to the target destinations. Hormones are involved in the

maintenance of physiological functions involved in day to day activities like sleep, feeding, and drinking etc., and also that with prolonged course of effects like reproduction, growth, aging, immunity, etc. (Kovacs and Ojeda 2012, pp. 1–3).

These hormone secreting glands are called “endocrine” which literally meant “to secrete within” indicating their mode of secretion. The target destinations of the hormones bear the specific receptors which upon binding induce signaling pathways involved in specific biological functions. There are eight such major along with many minor glands which are grossly conserved in animal kingdom (including human) and share similar morphology among mammals. Figure 1 is showing a schema of the major endocrine glands in male and female.

In general, the “endocrine system” comprises of three parts: a brain part – a nuclei of the hypothalamus, a pituitary gland part, and a target endocrine gland. Hypothalamic nuclei secrete releasing or inhibitory hormones, which either stimulate or inhibit anterior pituitary cells to secrete a stimulatory hormone, which will further act upon a target endocrine gland like adrenal, thyroid, or else, which secrete exit hormone(s) which will be taken through the blood circulation to the target organs or body parts containing

specific hormonal receptors for action. Exceptions to this three tier system are some specific cells existing inside some organs, or body parts which secrete specific hormones (Kleine and Rossmanith 2016, pp. 269–297; Kumar et al. 2018).

The endocrine system works in concert with the nervous and immune systems which also share their functionaries (Kovacs and Ojeda 2012, pp. 1–3). The branch of science dealing with the endocrine system is called “endocrinology,” which is now a well-developed branch enjoying the technological advancement for the investigatory and diagnostic tools in the field.

Being a physiological functionary “endocrine system” bears the sets of diseases which arise of hyper or hypo function of the specific endocrine glands or faults in their brain part regulations or receptor activation at target site. This chapter is dealing with the individual endocrine glands, their central and peripheral regulations, implied hormonal mechanisms, and related diseases/disorders to provide the readers a comprehensive view of the animal “endocrine system,” with a focus in human.

### History: A Brief Chronological Description of the Progress Made in Endocrinology

Earliest descriptions for the endocrine system are found about 200 B.C. when Chinese began isolating sex and pituitary hormones from human urine and using them for medicinal purposes. Later descriptions are from the medieval Persia by Avicenna, a legendary scientist, who provided a detailed account on diabetes mellitus in “The Canon of Medicine” (c. 1025), describing its clinical features as abnormal appetite, collapse of sexual functions, and sweet taste of urine.

In 1835 Irish doctor Robert James Graves described a case of goiter with bulging eyes (exophthalmos); the condition was later named after him as Graves’ disease.

In 1849, Thomas Addison described Addison’s disease (also known as primary adrenal deficiency or hypocortisolism). In the same year, Arnold

**Endocrine System, Fig. 1** Major endocrine glands in the human body

Berthold, who is regarded as a pioneer in endocrinology, observed that castration had negative effect on male cockerels who did not develop proper sex-specific characteristics. Later, in 1889 Brown-Séquard, a professor at the Collège de France, reported that self-administration of animal testes extracts led to enhancements in his physical strength, intellectual capacity, and sexual potency though it could not be replicated by the others. It could not be clarified further until 1904, the year Bouin and Ancel reasoned that some secretion from the Leydig cells is involved in the development of the male characteristics which were later named testosterone. Pure, crystalline testosterone was extracted not until 1935.

In 1889 when Joseph von Mering and Oskar Minkowski described hormonal etiology of the diabetes, they observed that surgically removing the pancreas resulted in an increase of blood sugar, followed by coma and eventually death.

In 1891, Murray successfully treated a female patient with myxedema with thyroid extract.

In 1894, Oliver and Schaefer described the presence of epinephrine in extracts from the adrenal medulla.

In 1902 William Bayliss and Ernest Starling in a unique experiment showed that acid instilled into the duodenum induced secretion in pancreas, even after removing any nervous connections between the two organs.

Nayliss and Starling discovered the hormone secretin in 1903 and also used the first the term “hormones” to indicate such chemical messengers.

In 1909, MacCallum and Voetlin stated an association between calcium metabolism and the parathyroid glands.

In 1913, Farmi and Von den Velden treated diabetes insipidus with posterior pituitary extracts.

In 1921 Otto Loewi first brought the idea of neurohormones and that year only growth hormone (GH) was first described by Evans and Long.

In 1922 Banting and Best discovered insulin. Insulin showed a magical effect on the health of the diabetes patients for whom otherwise no cure was available until then (Fig. 2). No later, Eli

Lilly, a chemist and owner of an American pharmaceutical company, started mass production of insulin (Fig. 3).

In 1962 Sutherland a renowned pharmacist reported that the action of epinephrine is mediated by secondary messengers like cyclic adenosine monophosphate (cAMP). It was a landmark discovery which unraveled the mechanism of the action of hormones.

## Evolutionary and Developmental Basis

Most animals with well-developed nervous/circulatory systems essentially have an endocrine system. The endocrine system of vertebrates consists of glands and diffuse cell groups scattered in epithelial tissues. Endocrine glands develop from all three germinal tissue layers (endoderm, mesoderm, ectoderm); hence, the type of endocrine product is determined by the tissue layer a gland originated in. Glands of ectodermal and endodermal origin produce peptide and amine hormones; but mesodermal-origin glands secrete steroid or lipid hormones (Sadler and Langman 2015; Kleine and Rossmanith 2016, pp. 347–353).

## Classification of Endocrine Glands

Endocrine glands can be classified as central and peripheral. Central endocrine glands are those which are present within the cranium and are part of the brain as hypothalamus, pituitary and pineal glands. The other glands existing outside the cranial premises are called peripheral. Endocrine glands also can be classified as primary and secondary endocrine organs. Primary endocrine organs have the only function to secrete hormones (Table 1a), but secondary endocrine organs are primarily meant for the other biological functions and also secrete hormones to support and sustain their primary functions (Table 1b). In secondary endocrine organs, only specific cell groups or tissue components would be devoted for the hormonal secretion. Pancreas, though merits to be a primary endocrine organ by definition, it is only partly endocrine, as it has only a specific cell

group (Islets of Langerhans) dispersed along whole length of organ (mainly tail part) which is endocrine, rest of the pancreas is exocrine – secretes enzymes meant for digestive functions which exit through ducts. Similarly, hypothalamus though considered as a primary endocrine organ, only neurons in the specific nuclear groups are endocrine. Table 1 enlists animal endocrine glands, exiting hormones, and their major functions.

## Endocrine Glands: Brief Anatomy and Hormone-Related Functions

### Primary Endocrine Organs

#### Hypothalamus

**Structure** Hypothalamus is the basal part of the diencephalon (its upper part is called thalamus)

making the floor of the third ventricle of the brain. The lower most part of this brain structure projects into the pituitary (infundibular) stalk making posterior or neurohypophyseal part of the pituitary gland. The specific nuclei groups of hypothalamus involved in the secretion of hormones are described below along with the functions.

**Function** Hypothalamus is the central regulator of the entire endocrine system. Hypothalamic neuronal cells secrete releasing/release inhibiting hormones which further stimulate/inhibit the synthesis of stimulating hormones from the anterior pituitary. Chiefly, arcuate nucleus of the tuberal region, and also some nuclear groups in preoptic and supraoptic regions, which control the secretion of hormones from the anterior pituitary, or the supraoptic and paraventricular nuclei (PVN) of supraoptic region of the hypothalamus which secrete oxytocin and vasopressin and corticotrophic releasing hormone (CRH)

*The First Insulin Commercially Available In the United States*

Iletin is the name that distinguishes the Insulin made by Eli Lilly and Company. It was the first Insulin commercially available in the United States.

The great demand for Iletin (Insulin, Lilly) necessitates the manufacture of large lots and has enabled us to develop methods of preparation and standardization that insure purity, stability and constant strength within narrow biological limits.

Patients who use Iletin (Insulin, Lilly) are afforded protection against disturbances which might follow a change from one lot to another if the lots in question were not uniform. A service wholesaler can supply Iletin (Insulin, Lilly) in such quantities as to help you secure a maximum turnover on a minimum investment.

*Lilly*

constitute endocrine part of the hypothalamus. Arcuate and other hypothalamic nuclei controlling hormonal secretion form the anterior pituitary

send their axons to the median eminence (hypothalamic extension which forms stalk of the pituitary gland) and emit their secretions

which get collected in the portal venous capillaries present there and through the portal veins reach to the anterior pituitary. Contrastingly, oxytocin and vasopressin are synthesized by the supraoptic and paraventricular nuclei of the hypothalamus, respectively, though are released at the posterior pituitary or neurohypophysis where their axons are ending. Hypothalamic endocrine function is regulated by the instructions from the higher cortical centers and also through the feedback received from the different hierarchical levels of the endocrine systems which are under the hypothalamic control (Kovacs and Ojeda 2012, pp. 116–148, Kleine and Rossmanith 2016, pp. 269–297). Hypothalamic endocrine regulation is further discussed in this chapter in section “Endocrine System: Physiological Regulations.”

### Pituitary Gland

**Structure** Pituitary gland is the master controller of all peripheral primary endocrine glands. This gland is located in the hypophyseal fossa (also called pituitary fossa) which is placed in the center of middle cranial fossa of base of the skull. Embryological derivation of this gland is unique. Posterior half of the gland is the extension of the hypothalamus hence neural and is called neurohypophysis. The neurohypophysis contains the axons terminals of the neurons supraoptic and PVN nuclei of the supraoptic region of the hypothalamus. Anterior part of the gland is derived from the evagination of the oral ectoderm in front of the buccopharyngeal membrane and is called adenohypophysis. Most of the pituitary hormones are

secreted from the adenohypophysis part except oxytocin and vasopressin or antidiuretic hormone (ADH) which are secreted from the neurohypophysis part (Kovacs and Ojeda 2012, pp. 116–171).

**Function** The hypothalamic releasing or inhibitory hormones regulate the synthesis of trophic hormones from the anterior pituitary through hypophyseal portal system (Fig. 4). Posterior pituitary hormones oxytocin and vasopressin regulate hemodynamic status of the body. Oxytocin is also involved in induction of the delivery and ejection of breast milk in female (Kovacs and Ojeda 2012, pp. 148–171). Both of the hormones have effect on animal social behavior, memory, and learning, especially oxytocin, which is also called social molecule (Kumar et al. 2018).

### Pineal Gland

**Structure** Pineal is a minute pine cone like gland located at the rear end of the diencephalon. The cellular elements of the gland are pinealocytes (approx. 95%) and neuroglia cells, and it is densely filled with afferent nerve terminals. The gland is highly vascular and rich in sympathetic innervations.

**Function** Pineal gland secretes (by pinealocytes) a serotonin-derived photoactive hormone melatonin which helps regulate circadian rhythm of the body (to regulate the sleep and wakefulness) in concert with the biological clock situated in the supra-chiasmatic nuclei (SCN) of the hypothalamus. It is also a known powerful antioxidant. Melatonin secretion is regulated by light exposure

### Endocrine System,

**Fig. 4** Hypophyseal portal circulation

and its intensity and shows a rhythmic secretion, being low during the daylight hours and high during dark periods.

Melatonin is also believed to be involved in sexual development and reproductive functions (blocks secretion of LH and FSH), thermoregulation, cellular metabolism, and also in immune function. Though there is little evidence in human that the pineal gland plays a significant role in the neuroendocrine regulation of reproduction during either puberty or adulthood, in seasonally breeding animals, such as sheep and hamsters, melatonin secretion is said to be influenced by the day length and thus gating reproduction as a function of the season (Kleine and Rossmanith 2016, pp. 243–244).

### Thyroid Gland

**Structure** Thyroid gland is situated in the neck extending from C5 to T1 vertebrae and is related with laryngeal cartilages and upper tracheal rings. It is a butterfly-like structure having two lobes and

a connecting isthmus that lies in front of 2–4th tracheal rings. The lobes lie on either side of the larynx and trachea and whole gland is covered by pretracheal fascia. In some individuals, an extra smaller lobe of thyroid called pyramidal lobe may be present, which may extend from the isthmus up to the hyoid bone.

**Function** Thyroid gland secretes hormones Tri-iodothyronine (T3) and Tetra-iodothyronine or Thyroxine (T4) which are involved in the regulation of the basic metabolic rate of the body (influencing physiological functioning of almost each cell and the organ). Thyroid hormones are secreted from the lining epithelial cells of the follicles which further go iodination in the colloid filled in the lumen of the follicles (Fig. 5). Iodine is exclusive to and an essential component of the thyroid hormones. The term “iodine” here refers to the elemental form of the iodine (I) which will get assimilated in the hormones in the iodide form ( $I^-$ ). Ingested iodine is absorbed through the small intestine and transported in the plasma to the

**Endocrine System, Fig. 5** Synthesis of Thyroid hormones. I: ionized iodine;  $I^0$ : oxidized iodine; Tg: thyroglobulin; TPO: thyroid peroxidase

thyroid, where it is concentrated, oxidized, and then incorporated into thyroglobulin (Tg) to form intermediate mono and diad (MIT and DIT) and later final and active triad (T<sub>3</sub>) and tetra (T<sub>4</sub>) forms of thyroid hormones in the thyroid follicles, and is stored there for a variable period (Fig. 5). Further, Tg base of the thyroid hormones undergo proteolysis releasing T<sub>3</sub> and T<sub>4</sub> into the circulation to be carried by specific binding proteins to target tissues. The synthesis of T<sub>4</sub> is about 4 times more than T<sub>3</sub>. Its vast influence is mediated through differential expression of hormone receptor isoforms in tissues and conversion of thyroxine (T<sub>4</sub>) to triiodothyronine (T<sub>3</sub>), by the enzyme 5'-deiodinase (Fig. 5). The thyroid hormone secretion is controlled by thyrotropin-releasing hormone (TRH) from hypothalamus and thyroid stimulating hormone (TSH) from anterior pituitary along with nutritional signals like availability of the iodine and carrier molecules, and also by the environmental factors like radiation, chemical exposure, drugs, and temperature. Calcitonin is a small polypeptide hormone secreted by the parafollicular or "C" cells of the thyroid. Calcitonin decreases blood calcium and increases blood phosphate level by suppressing the osteoclast activity in bones and increasing the amount of calcium excreted in urine (Kleine and Rossmanith 2016, pp. 269–297).

#### Parathyroid

**Structure** The small glands (about 50 mg), two each side, are normally found on the posterior aspect of the lobes of thyroid gland.

**Function** Parathyroid gland secretes parathyroid hormone (PTH) that controls calcium and phosphate homeostasis in the body. Effect of PTH on blood calcium and phosphate levels is opposite of calcitonin for which it is known as an antagonizing hormone.

#### Adrenal Gland

**Structure** Adrenal gland is a small gland located on the top of each kidney enclosed in renal fascia (alternative name for this is suprarenal gland). It

has cortical and medullary parts which secrete steroid and amine hormones respectively. The cortex is further differentiated into pars glomerulosa, fasciculata, and reticularis. Central medullary part contains chromaffin and ganglion cells of neural crest origin.

**Functions** Its cortical and medullary parts secrete distinct hormones which are involved in maintaining important physiological functions.

**Cortical Hormones** The pars glomerulosa, fasciculata, and reticularis secreting sex steroids or gonadotrophins, mineralcorticoids, and glucocorticoids or cortisol in order. All cortical hormones are steroid compounds derived from cholesterol.

**Gonadotrophins** The adrenal cortex secretes many male sex hormones, including DHEA, DHEA sulfate (DHEAS), androstenedione, and 11-hydroxyandrostenedione, and also small quantities of the female sex hormones progesterone and estrogen. Androgens secreted from the adrenal go extra-adrenal conversion to testosterone. These androgens have a role in early development of the male sex organs in childhood. They also mediate secondary sexual characteristics during puberty in the both sexes. ACTH from anterior pituitary has a physiological stimulatory effect on androgen release by the adrenal.

**Mineralocorticoids** Aldosterone accounts for most of the mineralocorticoid activity, with some contribution from glucocorticoids. The concentration of aldosterone in blood exhibits diurnal variation, and the secretory rate is generally 150–250 µg/day. Aldosterone promotes sodium reabsorption and potassium excretion by the tubular epithelial cells of the collecting and distal renal tubules thus way maintaining normal osmolality and water balance in blood. Reabsorption of sodium is followed by passive absorption of water, leading to an increase in the extracellular fluid volume with minimal change in the plasma sodium concentration.

**Glucocorticoids** Most of the glucocorticoid activity comes from cortisol, with corticosterone having a minor contribution. The normal blood cortisol concentration averages 12  $\mu\text{g/dL}$ , with an average secretory rate of 15–20 mg/day. Cortisol secretion from adrenal gland is the output hormone in HPA axis, and also it is the chief stress hormone in body. Other functions of cortisol are like counteracting insulin secretion, stimulating gastric-acid secretion, reducing bone formation, and functioning as a diuretic. Cortisol also contributes to the maintenance of various homeostatic actions, like blood pressure, immune system, metabolism of protein, carbohydrate, and fat, and anti-inflammatory action. Its secretion is controlled by the hypothalamo-pituitary-adrenal (HPA) axis, which follows a circadian rhythm and also gets influenced by exposure to the light and hours of the sleep (vice versa it regulates sleep) (Longo 2015, Chapter 399; Kleine and Rossmanith 2016, pp. 339–346). Its regulation through HPA axis and neural and molecular basis of rhythmic secretion are further discussed in this chapter in section “[Endocrine System: Physiological Regulations](#).”

**Medullary Hormones** The chromaffin and ganglion cells in the medulla secrete epinephrine/adrenalin and norepinephrine/noradrenaline and in minute amount dopamine. These hormones are secreted into the bloodstream as a result of direct stimulation by acetylcholine release from the sympathetic nerves. Preganglionic sympathetic nerve fibers reach to the chromaffin cells of the adrenal medulla without synapsing anywhere else. These hormones are responsible for the maintenance of cardiac output, physiological vascular resistance, and stress response (Kleine and Rossmanith 2016, pp. 269–297).

#### Ovary

**Structure** Ovary is the female gonad located in the pelvis one on each side at the terminal end (fimbria) of the uterine tube. A single follicle is the endocrine unit of the ovary. Each follicle contains a germ cell/oocyte at the core surrounded by an

inner and an outer layer composed of granulosa cells and theca cells, respectively.

**Function** It secretes the hormones which are essential for the maintaining functions and health of their reproductive organs. Ovary chiefly secretes estrogen and progesterone which are, respectively, responsible for the initiation and maintenance of the pregnancy, and also secretes androstenedione and testosterone in slighter amount which can get converted to estrogen with aromatization. Estrogen also shows a terminal surge which induces secretion of the oxytocin which in turn would initiate uterine contraction to facilitate delivery of the child. Ovary also secretes minor nonsteroidal hormones as activin, inhibin, and relaxin. Nonsteroidal ovarian hormones have a contribution in regulating production of steroid hormones though chief regulation is by LH and FSH by anterior pituitary (activin enhances, and inhibin and relaxin suppress). Relaxin also relaxes the hip ligaments before delivery of the child.

Estrogens also have effect on the physiological processes other than reproduction such as bone metabolism/remodeling, nervous system maturation, and endothelial responsiveness. Estrogen also brings pubertal changes in female like breast development and enlargement and maturation of the uterus, ovaries, and vagina. Estrogen also works in concert with growth hormone and insulin-like growth factor I (IGF-I) to produce a growth spurt and stimulates the maturation of chondrocytes and osteoblasts, which ultimately leads to epiphyseal fusion. Until midpuberty, estrogen begins to exert a positive feedback on gonadotropin-releasing hormone (GnRH) secretion, leading to the progressive increase of LH and FSH production, culminating in the LH surge, ovulation, and the initiation of the menstrual cycle. In the adult female, estrogen plays a critical role in maintaining the menstrual cycle (Kovacs and Ojeda 2012, pp. 194–238, Kleine and Rossmanith 2016, pp. 269–297).

#### Testes

**Structure** Testis is the male gonad which in contrast to the female gonad, along with the external

genitalia presents in the perineal region, present bilaterally enclosed in scrotal sac.

**Function** It chiefly secretes testosterone which is necessary for the gametogenesis and also development and maintenance of the male reproductive system and male sexual behavior. Higher center regulation of testosterone synthesis is much simpler than the female sex hormones due to absence of a defined cyclic period in male. The male sex hormones secreted from adrenal gland make additional source of this hormone through conversion.

#### Pancreas (Islet Cells)

**Structure** Islet cells of the pancreas which are dispersed among the exocrine acini as clusters constitute endocrine part of this organ. Islet cell clusters are more abundant towards rear part of the organ with highest density in the tail.

**Function** Islet cells secrete three types of the hormones: alpha cells secrete glucagon, beta cells insulin, and delta cells somatostatin, respectively, which are crucial for the normal metabolic functions of the body. Insulin and glucagon control the two opposite aspects of glucose metabolism, glycogenesis and glycogenolysis, respectively, in consequent control concentration of glucose in blood. Insulin is also involved in the metabolism of many other energy storing biomolecules which finally reduce blood glucose level.

#### Organs/Tissue Components with Secondary Endocrine Function

Certain animal organs contain a tissue component or specific cell groups with endocrine functions (Table 1b). Below is being provided a brief descriptions of such endocrine structures and their functions.

#### Placenta

**Structure** Placenta is an endocrine organ of pregnancy. All female mammals other than monotremes and marsupials (most) bear placenta during pregnancy. Placenta is implanted in the uterine

wall, where it receives nutrients and oxygen from the mother's blood and passes out excretory products. It is a disc like structure. Uniquely, it has maternal and fetal components both providing a physical link between the two. Maternal and fetal components are derived from uterine decidua (functional layer of the endometrium which is shed during parturition) and chorionic frondosum (an outer trophoblast shell and inner chorionic plate made of extraembryonic mesoderm), respectively (Sadler and Langman 2015, p. 112). It is the fetal component, especially the syncytial layer of the trophoblast cells, which is endocrine, and secretes hormones to sustain pregnancy.

**Functions** Placenta secretes progestins (mainly progesterone) along with the corpus luteum. It also secretes estrogen (especially weaker estriol) which inhibit the LH along with the progesterone to help sustain pregnancy and induce growth of the breast. During initial 2 months of the pregnancy, syncytial cells of the trophoblast secrete human chorionic gonadotrophin (HCG), which helps to maintain corpus luteum until placenta takes the action of synthesizing progesterone. HCG also inhibits LH like gonadotrophins to stop further ovulations and to help sustain pregnancy. This hormone is excreted in the maternal urine in initial months of the pregnancy and is used as a gestational indicator. Another hormone secreted by the placenta is somatomammotropin (placental lactogen), which is a growth hormone like substance, providing fetus a priority on maternal glucose and inducing maternal glucose synthesis hence making the mother functionally diabetic during pregnancy. It also helps growth of the breast in mother (Sadler and Langman 2015, pp. 116–117).

#### Thymus

**Structure** The thymus is a double lobed structure located in the upper anterior part of chest directly behind sternum. It has an outer zone called cortex and an inner zone called medulla. Histologically, the organ is composed of two types of cell called lymphocytes and reticular cells. The cortex bears the immature T cells

which migrate to the medulla in order to mature (Standring 2016, pp. 1362–1365).

**Function** Thymus produces hormones like thymosin (alpha 1), thymulin, and thymopoietin, which have been stated to circulate through blood and to act on both prothymocytes and mature T-cells in the periphery which helps to maintain commitment and functions of these cells. The hormones produced by the thymus promote the maturation of the T cells prior to their release into the blood. Once these thymic lymphocytes (or T cells) have fully matured in the thymus, they migrate to the lymph nodes in the body and guard against invader microorganisms or living or nonliving foreign particles causing diseases, a biological function called immune surveillance (Kleine and Rossmanith 2016, pp. 269–297; Standring 2016, pp. 1362–1365).

#### Adipose Tissue

Adipose tissue secretes several hormones. These hormones are mainly involved in lipid metabolism and storage. Adiponectin – a hormone synthesized by adipose cells – appears to reduce cellular insulin resistance and to protect blood vessels from inflammation and atherosclerosis. Leptin, synthesized by the adipose cells, acts as an indicator of satiety. It is released in response to food and acts on the neuronal regions dealing with the energy intake and expenditure (Kleine and Rossmanith 2016, pp. 269–297).

#### Skin

The skin cells synthesize inactive form of vitamin D<sub>3</sub>, cholecalciferol from cholesterol when exposed to ultraviolet radiation. Cholecalciferol is converted to an intermediate in liver, which further is converted to calcitriol – the active form of vitamin D<sub>3</sub>, in kidney. Vitamin D is important in a variety of physiological processes, including intestinal calcium absorption and immune system function (Kleine and Rossmanith 2016, pp. 269–297).

#### Skeleton

Bone cells secrete Fibroblast growth factor 23 (FGF23). Its action is to inhibit the formation

of calcitriol from vitamin D<sub>3</sub> and to increase phosphorus excretion from kidney. Osteocalcin, from the osteoblasts, induces insulin secretion from pancreas and also promotes its responsiveness on the peripheral tissues (Longo 2015, chapter 423).

#### Heart

Specialized cells in the atrium wall secrete the peptide hormone atrial natriuretic peptide (ANP) in response to distension caused by increased blood volume or pressure. ANP has a role in maintaining hemodynamic status of the body. It reduces sodium reabsorption and, in turn, decreases accompanied water reabsorption from the urinary filtrate in the kidney, bringing down the total blood volume. It also has an inhibitory effect on the renin secretion from the specialized cells of the kidney tubules, hence initiation of the renin-angiotensin-aldosterone system (RAAS) which has an opposite effect on hemodynamic balance in the body (Kleine and Rossmanith 2016, pp. 269–297).

#### Gastrointestinal Tract

The mucosa of the GI tract, mainly the stomach and small intestine, contains specialized cell which secrete hormones meant to help in the digestion. Like, G-cells in the stomach secrete a peptide hormone, gastrin, in response to distension caused by entering food that stimulates the release of hydrochloric acid from other cells. Similarly, secretin, a peptide hormone, is secreted by the small intestine in response to the acidic chyme released from stomach. Secretin stimulates the release of bicarbonate from the pancreas, antagonizes acidic chyme, and also inhibits the further secretion of hydrochloric acid by stomach mucosa. Cholecystokinin (CCK) is another peptide hormone released from small intestine which induces the secretion of digestive enzymes from pancreas and also the release of bile from the gallbladder. Intestinal hormones are also involved in glucose metabolism, like gastrin inhibitory peptide-1 (GIP-1) and glucagon like peptide-1 (GLP-1) secreted from the small intestine induce secretion of insulin (Kleine and Rossmanith 2016, pp. 269–297; Kumar et al. 2018).

## Liver

The endocrine function of liver is highly involved in metabolic regulation of the digestive nutrients. It synthesizes various hormones such as insulin-like growth factor (somatomedin), angiotensinogen, thrombopoietin, and hepcidin. IGF-1 has insulin-like effects as its name suggests, and it can bind to the insulin receptor. Its actions are mediated through a same named tyrosine kinase receptor which presents on the surface of almost all cells and is the stimulus for growth in the body. Angiotensinogen by the action of enzyme renin secreted from the kidney gets converted to angiotensin which is a substrate of Renin-Angiotensin-Aldosterone System (RAAS) maintaining hemodynamic balance in the body. Angiotensin also causes vasoconstriction (Kleine and Rossmanith 2016, pp. 269–297). Hepcidin is small peptide hormone majorly synthesized in the liver. It is chief regulator of the extra cellular excretion of the iron in the body (Gressner and Gressner 2018).

## Kidneys

Certain cells of kidney secrete hormones which are crucial for hemodynamic and electrolyte balance in the body. A decline in blood flow which is detected at the glomerular filtration system induces release of the enzyme renin, which in turn switches on the RAAS stimulating the reabsorption of sodium and water leading to increase in blood flow and blood pressure. The kidneys regulate blood calcium levels through the production of calcitriol from vitamin D<sub>3</sub>, which is released in response to the secretion of PTH. Low oxygen level in circulation induces synthesis of erythropoietin (EPO) from kidney which in turn would stimulate the production of red blood cells (erythrocytes) in the bone marrow, thereby increasing oxygen delivery to tissues (Mukoyama and Nakao 2005).

## Hormones

### Types and Structure

Hormones are mostly proteins, but some are also peptides, amines, or steroids. The protein, peptide,

**Endocrine System, Fig. 6** Cholesterol derivations of the lipid hormones

or amine hormones are water soluble, but steroid hormones are lipid soluble. Lipid-soluble hormones act slow, but their effects last longer than water soluble hormones (Kleine and Rossmanith 2016, pp. 11–17; Kumar et al. 2018). Lipid hormones have a common molecule of origin as cholesterol (Fig. 6). Most of the hormones are secreted by peripheral organs or specific tissue components. Some hormones are synthesized inside the brain which are called “neurohormones” (Table 2). Neurohormones also include some of the sex hormones (estrogen, progesterone, and testosterone) which are also synthesized by cortical neurons (Ish et al. 2007).

### Mechanisms of Action

Protein, peptide, and amine hormones (except thyroid hormones) are water soluble, hence cannot cross through the cell membrane directly. These hormones attach to the receptors present on the surface of target cells creating the hormone-receptor complex, in turn engaging a G-protein dependent secondary messenger pathway (like cAMP, cGMP, Diacylglycerol, Ca<sup>++</sup>, etc.,) to induce protein kinases/phosphorylases related to specific biological events. Steroid

hormones are lipid soluble, hence can cross through the cell membranes. They directly reach nucleus tagged with transporters or binding protein present in the cell cytoplasm, where they set free from the carrier molecule and attach to the nuclear receptors (binding sites) at DNA promoter regions for the genes assigned for forming specific

proteins (Fig. 7) (Kleine and Rossmanith 2016, pp. 263–267; Kumar et al. 2018).

Thyroid hormones, though chemically amine, are exception to the group. Their three dimensional structure resembles that of the steroid hormones, hence can enter the cell and reach to the specific nuclear receptors with the help of specific transporters present at the cell membrane (facilitated diffusion) and in the cell cytoplasm.

Hormones are biologically active in very minute amount which get usually measured in micrograms ( $\mu\text{g}$ ,  $10^{-6}$  g), nanograms (ng,  $10^{-9}$  g), or picograms (pg,  $10^{-12}$  g). Hormone-Receptor interactions for all categories of hormones are highly specific, reversible, and satiable and follow a threshold limit for the maximal biological response (i.e., follow normal distribution curve). Also, there is differential purposing of the category of hormones depending on the metabolic processes involved. Metabolic processes which need urgent response, such as blood glucose or calcium homeostasis, are usually controlled by peptide hormones (also epinephrine), but processes for which response is slow, such as pubertal development or basic metabolic rate, are controlled by steroid hormones and thyroid

**Endocrine System, Table 2** Neurohormones

|                                                   |                                      |
|---------------------------------------------------|--------------------------------------|

hormones. Electrolyte homeostasis requires intermediate response speed and is regulated by peptide and steroid hormones both (Kleine and Rossmanith 2016, pp. 263–267).

**Hormone Secretion, Transport, and Degradation**

The blood level of a hormone is determined by its rate of secretion and its circulating half-life. After protein processing, peptide hormones are stored in secretory granules, from where are later released into the circulation. The stimulus for hormone secretion may be a releasing factor or neural signal that induces rapid changes in intracellular calcium concentrations, leading to secretory granule fusion with the plasma membrane and release of the hormones. In contrast, steroid hormones diffuse into the circulation as they are synthesized hence their secretory rates are closely aligned with rates of the synthesis.

Hormone transport and degradation determine the speed with which a hormonal signal may decay. Some hormonal signals are short decaying (e.g., somatostatin), whereas others are longer-lived (e.g., TSH). An understanding of circulating hormone half-life is necessary for the proper physiologic hormone replacement (Longo 2015, chapter 399).

**Crossing Blood Brain Barrier (BBB)**

Transport of a hormone through blood brain barrier (BBB) depends on whether it is water or lipid soluble. Steroid hormones are lipid soluble, hence can easily pass to and fro through the BBB (the peripherally synthesized hormones enter brain and those synthesized inside brain reach to periphery), but protein, peptide, amine, and other hormones which are water soluble can do it with help of the transporters/binding proteins only. Transport of the lipid insoluble hormones is a saturable/rate limited process due to exhaustion of the transporters/binding proteins (Banks 2012; Kumar et al. 2018).

Certain of the hormone synthesizing brain regions, called circumventricular organs, are devoid of a blood brain barrier (BBB) which facilitates the release of the stored hormones in the blood (Table 3) (Kumar et al. 2018).

**Endocrine System, Table 3** BBB free regions in brain

|                                            |
|--------------------------------------------|
| Circumventricular organs                   |
| 1. Organum vasculosum of lamina terminalis |
| 2. Subfornical organ                       |
| 3. Subcommissural organ                    |
| 4. Median eminence (hypothalamus)          |
| 5. Intermediate lobe of pituitary gland    |
| 6. Posterior pituitary                     |
| 7. Pineal gland                            |
| 8. Area postrema (4th ventricle)           |

These BBB-free regions are also the site for receiving peripherally released hormones. These brain regions contain receptors for the peripheral hormones – presenting a unique opportunity for neuron-hormone interactions.

**Endocrine System: Physiological Regulations**

**Central Endocrine Axes and Hormonal Homeostasis**

The endocrine system is governed by the central axes which essentially connects three components of the system: a brain component – a nuclei of the hypothalamus, anterior part of the pituitary gland, and any of the endocrine glands as adrenal, gonads, or thyroid. Each axis is regulated by the feedback cycles (Fig. 8) (Kleine and Rossmanith 2016, pp. 299–338; Kumar et al. 2018). Table 4 mentions the central axes, their essential components, and secreted hormones.

Central endocrine axes run from hypothalamus to adrenal, gonads, or thyroid via anterior part of pituitary (adenohypophysis). Hypothalamus in association with anterior pituitary and adrenal gland constitutes HPA axis – which bears an influence on most of the neurophysiological functions and is crucial for the neuroendocrine adaptation to the stress. A parallel axis connecting hypothalamus and anterior pituitary to gonads (testis in male and ovary in female) constitutes HPG axis which regulates reproductive functions.

In HPG axis, releasing/inhibitory hormones are secreted from specific hypothalamic nuclei which induce synthesis/release of stimulating/ luteinizing hormones from anterior pituitary which in turn induce synthesis/release of sex

hormones from the gonads. The peripheral endocrine glands and their central regulatory centers work in coordination in an attempt to maintain a state of functional equilibrium or physiological homeostasis in the body (Kleine and Rossmanith 2016, pp. 299–338).

Feedback regulation also occurs for endocrine systems that do not involve the central axes, for example, calcium feedback on PTH, glucose inhibition of insulin secretion, and leptin feedback on the hypothalamus.

Uniquely, prolactin a hormone secreted from the anterior pituitary essential for the control of the lactation in female and many other functions has only two components in its regulatory axis- (hypothalamo-prolactin axis) which does not contain an inter-gland feedback loop. The dopamine secreted from the tubero-infundibular nuclei of the hypothalamus is inhibitory to the secretion of prolactin from the anterior pituitary and also sets auto-inhibition of its own secretion (Macleod et al. 1981).

Paracrine and Autocrine Regulation

*Paracrine regulation* refers to factors released by one cell that act on an adjacent cell in the same tissue, such as somatostatin secretion by pancreatic islet cells inhibits insulin secretion from nearby cells. *Autocrine regulation* states the action of a factor on the same cell from which it is produced, such as IGF-I acts on the cells that produce it to regulate its secretion.

**Endocrine System, Fig. 8** Feedback regulations at central endocrine axes

**Endocrine System, Table 4** Central endocrine axes in the animals (including human)

| Name                                       | Hypothalamic component/hormone                                        | Pituitary component/hormone                                                                  | Target endocrine organ/hormone |
|--------------------------------------------|-----------------------------------------------------------------------|----------------------------------------------------------------------------------------------|--------------------------------|
| Hypothalamic-pituitary- adrenal (HPA) axis | Paraventricular nucleus (PVN)/ corticotrophin releasing hormone (CRH) | Adrenocorticotrophs, anterior pituitary/ adrenocorticotrophin hormone (ACTH)                 | Cortisol/ cortisone            |
| Hypothalamic-pituitary-thyroid (HPT) axis  | Paraventricular nucleus PVN/thyrotrophin releasing hormone (TRH)      | Thyrotrophs, anterior pituitary/thyroxine stimulating hormone (TSH)                          | Thyroxine 3 and 4 (T3 and T4)  |
| Hypothalamic-pituitary-gonadal (HPG) axis  | Arcuate nucleus/gonadotrophin releasing hormone (GnRH)                | Gonadotrophs, anterior pituitary/follicle stimulating hormone (FSH)/luteinizing hormone (LH) | Estrogen/ progesterone         |

Circadian Control of Endocrine Functions

SCN and PVN nuclei of hypothalamus regulate circadian release of hormones. Pineal gland is also known to maintain circadian release of melatonin which depends on exposure of the organism to the light. The circadian release of any hormone from the hypothalamic and pineal nuclei is affected by the duration and intensity of the light exposure. The SCN and other hypothalamic nuclei are connected to the retina – screening portal of the light, through bidirectional retinohypothalamic connections. Pineal gland nuclei are also connected to this circuitry through to and fro channels. Control of circadian rhythm through hypothalamic nuclei is a complex biological process which is genetically determined and conserved among species (Tsang et al. 2014; Andreani et al. 2015). The molecular repertoire maintaining circadian rhythms (Table 5) are not present only in the endocrine organs but in many organs and tissues, which together create a complex molecular network system with a central command from SCN (Hughey and Butte 2016).

Cortisol, the HPA axis output hormone, also follows circadian rhythm, with its peak secretion in the morning at 8 AM with lesser serum values along the day, with minimum at 4 PM. A dysregulation of circadian synthesis/release of the hormones is implicated in metabolic syndromes and neuroendocrine disorders including stress-induced psychiatric disorders and sleep disorders (Kleine and Rossmanith 2016, pp. 299–338; Kumar et al. 2018).

Endocrine-Nervous-Immune Cross-Regulation

Endocrine system is an autonomous but not a completely independent physiological unit. It has noted cross regulation with the nervous and immune system – which meant that hormones interact with the neuropeptides/neurotransmitters and immune cell derived cytokines. Evidence suggests that interaction between these systems is bidirectional and a dysregulation of it implicates in etiogenesis of the diseases like metabolic and psychiatric disorders (Kelley 1988).

Effects of Aging on Endocrine System

Most hormone levels decrease with aging. Salient hormones which decrease with aging are GH, IGF-1 and melatonin, and sex hormones like DHEA, estrogen, and progesterone. Decline of the melatonin may play an important role in the loss of circadian rhythms with aging. Sex hormone-binding globulin is reported to increase with age in both sexes. Levels of some hormones may also increase, like LH and FSH, and pancreatic polypeptide and gastrin (but not other gut hormones). For some hormones, their levels remain near normal with aging, these are thyroid (except T3, which is reduced possibly due to decrease conversion from T4). Parathyroid hormone shows an increase that may be due to decreased renal excretion. Adrenal cortical hormones like glucocorticoid and mineralocorticoid show higher serum concentrations with aging though the target organ for mineralocorticoid activity (kidney), however, becomes less responsive. For adrenal medullary hormones like epinephrine and norepinephrine, their baseline serum concentrations increase with aging though stimutable increases in both (as percentages of the basal concentrations) show a decrease. The circadian patterns for the hormones showing diurnal variation like cortisol, norepinephrine, and growth hormone are altered in aged.

In female, fall of the female sex hormones (estrogen and progesterone) is marked by menopause near the age of 45 years with rise of LH and FSH (LH initially may show a fall at commencement of menopause). In males, there is a gradual

fall of testosterone and increase of LH and FSH with aging called andropause. Insulin secretion is impaired and insulin resistance increases with age. Levels of androgens in female and estrogen in male may not show much change with aging (Chahal and Drake 2007).

## Endocrine Disorders

Each endocrine organ has specific disorders which may alter functions of the related physiological systems. Certain of the endocrine diseases/disorders present as the syndrome involving many organs. Endocrine disorders can result from dysfunction originating in the peripheral endocrine gland itself (primary disorders) or under stimulation or overstimulation by the central regulators of an endocrine axis as anterior pituitary, or hypothalamic nuclei (secondary disorders). The disorders can result in hormone overproduction (hyperfunction) or underproduction (hypofunction). Rarely, endocrine disorders (usually hypofunction) occur because of reduced responses from the target site receptors (Longo 2015, chapter 399; Kleine and Rossmanith 2016, pp. 357–376).

Endocrine disorders may also happen from exogenous or self-administration of a hormone, or due to a blockade in the regulatory axis for an endocrine gland (such as HPA axis), or in response of a diseased state (Longo 2015, chapter 399).

Hypofunction of a peripheral endocrine gland can be caused by congenital (like a genetic disorder resulting from deletion of a gene), or acquired disorders (like autoimmune and vascular disorders, tumors, infections, toxins, or hormone receptor hypofunction). Some hormones require conversion to an active form after secretion from the synthesizing gland, which may happen in some other glands, a dysfunction of the organ where activation has to take place, may result in hormonal hypofunction. For example, inactive form of Vitamin D is synthesized in the liver which requires further modification in kidney and skin, respectively, to become active, a disease of kidney or skin may result in hypofunction of vitamin D. Primary hyperfunction of endocrine

glands generally results from hyperplasia or neoplasia of the gland. Other reasons for this can be ectopic production of a hormone from a different tissue as may happen in cancers and autoimmune diseases (as in hyperthyroidism of Graves' disease). Table 6 provides a detailed list of endocrine diseases/disorders with anatomical and functional abnormality for each.

## Commonly Used Investigations

The concentration of hormones in blood or serum in the living animal can be investigated with the immunoassays (radio-, enzyme-, and fluorescence-immunoassay) and more recently high-performance liquid chromatography (HPLC) and mass-spectrometry combined with gas chromatography (MS–GC). The general investigations used for in vitro determination of hormones or their receptors are immunocytochemistry (ICC), autoradiography, in situ hybridization, and blotting. Medical imaging techniques (like PET scan and f-MRI) which reveal organ activation during certain actions or behaviors, paired with endocrine manipulations or monitoring, can provide important information (Fusani 2017). For human cases, taking patient history and clinical examination is the first thing to be done for an endocrine disorder, which would pave the way which tests should be conducted to reach a diagnosis. Hematology and urinalysis provide important information in diagnosing endocrine disorders. Other investigations are available to test the function of specific endocrine glands. Medical imaging like CT and MRI scans, sonography, and scintillation counting are useful for detecting change in the size of endocrine glands and the presence of tumors or cysts. Karyotyping for the chromosomal errors, or genotyping, or sequencing for mutation analysis, and genomewide association study for single nucleotide polymorphisms (SNPs) or copy number variations (CNVs) are also done for the disorders where a genetic basis is speculated (Fusani 2017; Kumar et al. 2018).

## Common Therapeutic Approaches

Control of the hypersecretion (surgical removal, radio or chemosuppression, or using a

|                                |                            | bleeding or loss of blood supply                                                                                                                                                                                                                                            | dizziness, headache, occasional loss of consciousness                                                                                  |                                                                                         |                                                                                                                    |             |
|                                | Central diabetes insipidus | Damage to the pituitary gland (or hypothalamus) disrupting the normal production, storage and release of ADH<br>Due to surgery, a tumor, an illness (such as meningitis), inflammation or a head injury or an inherited genetic disorder (in children), of an unknown cause | Intense thirst even after drinking fluids (polydipsia), and excretion of large amounts of urine (polyuria), electrolyte imbalance      | Urine and blood tests, water deprivation test.<br>Investigations for underlying causes  | Medication (desmopressin a synthetic ADH analogue), management of water loss, electrolyte imbalance and water loss |             |
| <b>Thyroid and parathyroid</b> | Hyperthyroidism            | Excessive production of thyroid hormones due to autoimmune conditions (Graves disease) or inflammation                                                                                                                                                                      | Restlessness, agitation, anxiety, tremors, weight loss, sweating, rapid heart rate, intolerance to heat, and, frequent bowel movements | Blood hormone analysis, tests for specific antibodies                                   | Medication, radioactive iodine therapy                                                                             |             |
|                                | Hypothyroidism             | Low production of thyroid hormones due to autoimmune conditions or inflammation, surgery, radiation, drug induced                                                                                                                                                           | Tiredness, feeling cold, weight gain, dry skin, constipation, and swelling (edema) of the face or ankles                               | Thyroid hormone analysis, increased blood TSH                                           | Thyroid hormone replacement                                                                                        |             |
|                                | Thyroiditis                | Excess/low production of thyroid hormones due to autoimmune conditions ((Hashimoto's thyroiditis) or infections, hypersensitivity                                                                                                                                           | Sign and symptoms of hyper/hypo thyroidism                                                                                             | Testing for the thyroid peroxidase (TPO) antibody in the blood/thyroid hormone analysis | Depending on the hormonal analysis                                                                                 |             |
|                                | Tumors                     | Benign and cancerous                                                                                                                                                                                                                                                        | Pressure in the neck, hoarseness of the voice, or difficulty in swallowing or breathing, metastatic symptoms                           | FNAC (biopsy), radioisotope scan                                                        | Surgical removal, radioactive iodine therapy                                                                       |             |
|                                | Hyperparathyroidism        | Excess parathyroid hormone (PTH) in the blood, caused by                                                                                                                                                                                                                    | Increased blood calcium levels can cause symptoms of                                                                                   | Blood hormone analysis                                                                  | Calcium monitoring, surgery                                                                                        | (continued) |

**Endocrine System, Table 6** (continued)

| Glands         | Disorders                                                    | Pathology/causes                                                                                                                                                                                                                                                                             | Signs and symptoms                                                                                                                                                                                     | Diagnostic investigations                                 | Management                                 |
|----------------|--------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------|--------------------------------------------|
| <b>Adrenal</b> |                                                              | tumorous growth in parathyroid gland                                                                                                                                                                                                                                                         | tiredness, poor concentration, low mood, bone pain, and stomach or abdominal symptoms                                                                                                                  |                                                           |                                            |
|                | Hypercortisolism                                             | Excess production of adrenal hormone cortisol secondary to Cushing's syndrome or an adrenal tumor                                                                                                                                                                                            | High blood pressure, weight gain, thinning of the skin, easy bruising, poor wound healing                                                                                                              | Blood and/or urine testing                                | Medication, surgical removal of the tumor  |
|                | Hyperaldosteronism                                           | Excess production of adrenal hormone aldosterone due to a tumor or nodular disease                                                                                                                                                                                                           | Low potassium in the blood and high blood pressure resistant to treatment                                                                                                                              | Blood test, <b>adrenal vein sampling</b>                  | Medication, surgical removal of the tumor  |
|                | Adrenal insufficiency                                        | Reduced hormone secretion from the adrenal gland, resulting in deficiency of all adrenal hormones, including cortisol and aldosterone. Reasons may be autoimmune destruction of the adrenal gland (Addison's disease), bleeding into the adrenal glands, or infections, such as tuberculosis | Weakness, weight loss, dizziness, and sometimes abdominal pain, nausea, and vomiting                                                                                                                   | Blood hormone analysis, screening for specific antibodies | Hormone replacement                        |
| <b>Ovary</b>   | Adrenal masses                                               | Mostly benign and rarely cancerous tumors. May produce excess adrenal hormones                                                                                                                                                                                                               | Symptoms of hyperaldosteronism and corticosisolism                                                                                                                                                     | Ultrasound, CT and MRI, histopathology                    | Clinical monitoring, surgery               |
|                | Ovarian insufficiency (sometimes called premature menopause) | Ovaries either do not develop, or are damaged hence no longer function normally                                                                                                                                                                                                              | Symptoms of low estrogen can develop in many, but not all: hot flashes, night sweats, poor sleep, and vaginal dryness. Infertility and the loss of the beneficial effects of estrogen and progesterone | Blood hormone analysis                                    | Hormone replacement                        |
|                | Polycystic ovary syndrome (PCOS)                             | Small cysts in the ovaries, increased amount of                                                                                                                                                                                                                                              | Irregular menstrual periods, loss of fertility, increased hair growth on the face, chest, or                                                                                                           | Blood tests for sex hormone, ultrasound                   | Ovulation induction by medication, surgery |

pharmacological agent as the antagonist) and replacement or correction of the deficiency (by pharmacological or dietary means, or treating the causes) are the main stream approaches for treating the endocrine disorders (Longo 2015, chapter 399–409). Recently, gene-based therapeutic approaches have shown promises for this where a genetic basis is known. Known gene-based approaches are either correction of the faulty genes through genomic editing or gene supplementation or using antisense oligonucleotides against the targeted genes. Gene therapy is considered more suitable for correcting the monogenic endocrine disorders like GH deficiency or familial hypercholesterolemia, though newer advances in gene-based therapy have also raised hope for the multifactorial diseases like diabetes mellitus or endocrine cancers, and obesity (Barzon et al. 2000). In case of autoimmune endocrine disorders, targeting the genes coding for the culprit immune molecules has been a successful approach. Suicide gene therapy (using a tumor and/or tissue specific gene which converts a pro-drug into a toxic substance which would kill the tumor cell) has been successfully used to treat endocrine tumors (Barzon et al. 2000).

## Endogenous Oscillations

Cristianna Colella

Department of Biology, Queens College, City University of New York, Flushing, NY, USA

### Definition

Endogenous oscillations are rhythmic intrinsic physiological processes by which biological systems establish time.

### Introduction

Endogenous oscillations refer to the naturally occurring mechanism by which biological systems mediate a wide array of rhythmic physiological and behavioral changes in organisms. In mammals, these highly conserved rhythms/cycles assume an approximate 24-h period, in the absence of external cues (i.e., zeitgebers), such as light.

Because the intrinsic biological clock maintains its periodicity in the absence of external cues, it is said to “free run.” Though the internal biological clock can keep time on its own, it tends to synchronize or “entrain” to environmental stimuli, primarily light, hence roughly the period of one solar day. Entrainment of the biological clock to light (as well as subsequent physiological responses) is mediated by the suprachiasmatic nucleus (SCN) of the hypothalamus (Partch et al. 2014). The coordinated actions of both the suprachiasmatic nucleus and the endogenous oscillators are collectively known as the “biological clock.”

## Molecular Mechanism

The SCN is considered the “master pacemaker” of the biological clock, due to its ability to synchronize the clock to the environment. However, the concept of timekeeping is fundamental to all cells. On a transcriptional level, this is achieved through the rhythmic/oscillating expression of clock genes.

At the center of the molecular mechanism underlying this biological clock is an auto-regulatory transcription-translation feedback loop (TTFL) whose cycle duration reflects the rhythmic/oscillatory expression of clock genes over the course of a day. The rhythmic fluctuations in abundance of resulting protein products determine their participation in either the positive arm or the negative arm of the loop, where they can facilitate or inhibit their own expression, respectively.

Though first discovered in the fruit fly, *Drosophila melanogaster*, the TTFL model for circadian rhythm is highly conserved across species and cell types. In mammals, the TTFL is composed of circadian oscillator proteins, which exist as homologues of *Drosophila* counterparts: the TTFL is initiated upon the formation of a transcriptional activation complex, Bmal1/CLOCK, consisting of brain and muscle Arnt-like 1 (Bmal1) and circadian locomotor output cycles kaput (CLOCK), which drives transcription of the core clock genes *periods* (*mPer1*, *mPer2*, *mPer3*) and *cryptochromes* (*mCry1*, *mCry2*). As Per and Cry proteins accumulate, they heterodimerize to form a Per/Cry complex, which in turn feed back to repress Bmal1/CLOCK, and turn off transcription of *mPer* and *mCry* (Partch et al. 2014). Degradation of residual Per and Cry proteins then permits the recommencement of the loop. In this way, Per and Cry are considered to be negative regulators of the TTFL, which maintain the circadian periodicity of the clock and operate in a light-independent fashion. The delay/lag in gene transcription, protein translation, accumulation, modification, and dynamics account for the cyclical nature of the expression of clock genes throughout the day.

## Effect on Behavior

Precise regulation of the transcriptional and post-transcriptional mechanisms driving core clock component dynamics is essential for temporal homeostatic control. Not surprisingly, dysregulation of the TTFL and/or mutations in core clock components is associated with disruptions in sleep-wake cycle (i.e., alterations in free-running period and phase of the clock) and genetic sleep conditions.

Polymorphisms in human *Cry1* are associated with delayed sleep phase disorder (DSPD), a common variant of insomnia characterized by late sleep onset (Patke et al. 2017). In the absence of the primary entrainment cue, light, *Cry* mutant mice demonstrate altered circadian rhythms and aberrant daily activity patterns. *Cry1* and *Cry2* mutants possess shortened and increased period lengths, respectively, and result in early or delayed daily activity onset, while *Cry* knockout mice display activity patterns that are entirely arrhythmic. This suggests an antagonistic role of *Cry1* and *Cry2* in modulation of the period and alignment of the internal clock and demonstrates the necessity of *Cry* proteins for setting the endogenous/internal clock (van der Horst et al. 1999).

Disruptions in the rhythmic posttranslational modification of *Per* proteins are linked to familial advanced sleep phase syndrome (FASPS), a sleep disorder characterized by early sleep onset and early awakening (i.e., morning insomnia; see Vanselow et al. 2006).

## Conclusion

Endogenous biological rhythms represent ubiquitous and robust timekeeping systems common to nearly all organisms. Biological rhythms are generated and maintained by the temporal dynamics of molecular components of a highly conserved autoregulatory transcription-translation feedback loop (TTFL). The duration of the cycle is reflected in peripheral tissues by the time-delayed light-independent/endogenous oscillations in TTFL clock gene expression,

which can be aligned to exogenous inputs by the suprachiasmatic nucleus of the hypothalamus. The resulting phasic expression drives time-dependent physiological and behavioral processes at the organismal level. Dysregulation of this loop results in impaired sleep-wake function and poor temporal homeostatic control, thereby causing negative physiological and psychological outcomes.

## Endoparasite

Madhavi Ranjan

Department of Life Sciences, Central University  
of Jharkhand, Brambe, Ranchi, India

### Definition

Endoparasite is a type of organism that harbors inside the host organism and is dependent on host organisms for their continuous source of nutrients and survival.

### Introduction

Parasitism is a type of symbiotic relationship between two same or different species where among them, one organism is known as parasite (which gets the benefit of relationship), while the other one which bears the loss in relationship is known as host (Cox, 2002). Parasites are generally host-specific and need specialized structures to invade the host. The host for parasite can be definitive or intermediate. The host which allows the parasite to attain maturity and multiply is known as definitive or primary host. However, some hosts that allow the parasite to reside for short transition period only to complete some developmental stages but not to reproduce are known as intermediate or secondary host. For instance, both malarial parasite of genus *Plasmodium* and sleeping sickness parasite of genus *Trypanosoma* have infective stages in the intermediate host cell that is further transferred to definitive host by insects' bites (Politt et al., 2011).

## Endoparasite

Parasites are classified as endoparasite and ectoparasite. The parasite residing inside the host body is termed as endoparasite, while ectoparasite is those residing outside, i.e., on the surface of the host body. Hookworms, tapeworms, and liver flukes are some endoparasites, whereas ticks,

fleas, and mites come under ectoparasites. Endoparasites are further differentiated as intercellular (inhabits spaces inside the host's body) or intracellular endoparasite (inhabits cells in host's body).

### Synonyms

Intermediate phenotype

### Definition

Literally, “endo” means internal or inside, and “phenotype” means immediately observable signs and symptoms. Thus, an endophenotype is a quantitative biological trait that is reliable and reasonably heritable, i.e., shows greater prevalence in unaffected relatives of patients than in the general population, but not easily observed on the surface.

### General Features of Endophenotype

Gottesman and Gould (2003) have outlined certain features of endophenotype as listed below:

1. The endophenotype is a quantitative biological trait that is heritable and associated with illness in the population.
2. Endophenotype and illness (appearance of a disorder) co-segregate within families.
3. The endophenotype is primarily state independent (always appears in an individual irrespective of the status of symptoms).
4. The endophenotype shows greater prevalence in unaffected relatives of patients than in the general population. It varies continuously in the general population.
5. Endophenotypes are associated with causes rather than effects of disorders.
6. Numerous endophenotypes can affect a given complex disorder.
7. Endophenotypes affecting multiple disorders could be found in genetically related disorders.
8. Endophenotypes should optimally be measured across several levels (genetic and or behavioral) of analysis.

In contrast to a monogenic or Mendelian disorder, a complex disorder results from a polygenic matrix whose individual components contribute only a small portion of the total risk. Researchers have found endophenotypes for many psychiatric disorders, including anorexia, autism, obsessive-compulsive disorder, and attention deficit disorder. But the most promising candidates of endophenotypes so far have come from the study of schizophrenia. A complex disorder like schizophrenia (a neurodevelopmental disorder that affects thinking, feeling, and behavior of a person) is the sum of many candidate intermediate phenotypes which used to be functionally associated with variant alleles and core clinical manifestation of the disorder quantitatively (Preston and Weinberger 2005) (Fig. 1). Some examples of such candidates are like P50 suppression, prepulse inhibition, antisaccade, mismatch negativity (MMN), and P300 event-related potential (Braff and Freedman 2002). In schizophrenia, the candidate endophenotypes are more likely to be modeled by a less complex genetic architecture than the disorder as a whole, i.e., the intermediate phenotypes have a less complex relationship to susceptibility genes (or variant alleles) than the

**Endophenotype, Fig. 1** Schematic diagram showing the relationship between genes, endophenotypes (EPs), and disorder

diagnostic phenotype based on statistical significance.

Importantly, the precise means by which a concentration of intermediate phenotypes might explain the clinical presentation of schizophrenia is yet to be determined. Hence, it is also conceivable that schizophrenia is more than a simple sum of distinct traits. In this view, phenotypic expression of the disorder requires the complex interaction of genetic and epigenetic matrices and, to some extent, the influence of environmental factors, acting perhaps through a final common pathway (Egan and Goldberg 2003) (Fig. 2).

## Endophenotypes of Some Common Medical Disorder

The endophenotype of some common medical disorders such as coronary heart disease (Cipollone et al. 2004), hypertension (Schwartz et al. 2004), depression (Goldstein et al. 2014), colon cancer, hereditary hemochromatosis (HH) (Pietrangelo 2004), and type 2 diabetes mellitus (Carlsson et al. 2005) has been studied. These are similar to psychiatric disorders as they arise from a polygenic matrix, each of which shows a relatively small contribution to the total risk. In the case of diabetes, insulin receptor resistance is an endophenotype because it has been viewed as an intermediate between several susceptibility genes and clinical diabetes. For

**Endophenotype, Fig. 2** Genome and environmental factors affect the endophenotype of an individual, and finally by acting through common pathway, they regulate the external phenotype, i.e., phenotypic expression of the disorder

depression, neuroticism, frontal asymmetry of cortical electrical activity, morning cortisol, reward learning, and biases of attention and memory have been found as endophenotypes. Similarly, colon polyps are intermediate phenotypes related to colon cancer. In hereditary hemochromatosis (HH), a clinical disorder of iron metabolism, studies of genetic susceptibility are good examples of the intermediate phenotype and the “gene of susceptibility” concepts. A quantitative measure of serum transferrin saturation was first to identify endophenotype in HH (Pietrangelo 2004), which led to the recognition of high prevalence of a mutation carrier hemochromatosis gene (*HFE*). The *HFE* codes a membrane protein that associates with  $\beta$ 2-microglobulin and regulates iron absorption by regulating the interaction of the transferrin receptor with transferrin. Thus, *HFE* gene is recognized as a gene of susceptibility in HH.

Since a long time, psychiatric research has interested in developing reliable biomarkers with clinically significant biological features which are associated with psychopathology. A valid biomarker could help to improve diagnosis, prognosis, and treatment as well as provide clues to the nature of underlying pathophysiology (Iacono 1985). There are many biomarkers like

neurochemical metabolites or measures of inflammatory response that have been reported for the vast majority of disorders. But, there is a lack of consensus regarding which molecule will act as the best marker target. So, identifying a valid biomarker from a vast array of putative biochemical markers is still an intimidating task. Endophenotypes have been recognized as biomarkers. To be addressed as a good biomarker for psychiatric research, an endophenotype construct should be validated by certain criteria which are grouped into three domains (Iacono et al. 2017) (Fig. 3).

1. **Threshold criteria** depict the minimum requirements for any biomarker to stand as a putative endophenotype.
2. **Endophenotype verification** identifies the requirements necessary to remove the qualifier “putative” or “candidate” from an endophenotype’s status. Compared to the first domain, there is far less endophenotype research targeting verification.
3. **Utility** shows the usefulness of an endophenotype, i.e., how a verified endophenotype can be used as a research tool to study the biological etiology of psychiatric disorder as well as identification of molecular genetic variants associated with psychopathology.

**Endophenotype, Fig. 3** Endophenotype construct validation. Steps and components involve in construct validation of an endophenotype

## Conclusions

According to the central dogma, the fundamental unit of genetic transmission is an abnormality in the structure or function of a protein. Such abnormalities in protein affect neuronal function which reflects changes in physiological functions, i.e., endophenotypes. The analysis of alone or combined contribution of different genetic abnormalities to neuronal pathophysiology of a psychiatric disorder may help in the study of psychotic illnesses in depth and point the way to new treatment approaches. The endophenotypes are measurable and heritable biological traits that are related to complex psychiatric disorders such as schizophrenia and reflective of genetically based disease mechanisms. The identification and study of endophenotype help to uncover genetically mediated risk/vulnerability factors that often interact with nongenetic factors to produce psychiatric disorder like schizophrenia. Thus, endophenotype-based strategies can play an important and informative role in diagnosis and treatment of the complex psychiatric.

## Introduction

The dorsal ventricular ridge (DVR) is the main body of mass that forms the avian telencephalon. The DVR contains the major pallial regions of the avian brain, including the nidopallium (N), mesopallium (M), arcopallium (A) and, nested among these areas, the entopallium (E). Based on its afferent and efferent projections, the effects of lesions to the area, and single-unit electrophysiological data, the E is a higher-order visual and motion processing structure and is considered analogous to some region of the primate extrastriate cortex.

## Anatomy of Entopallium

In most avian species, the E is a large curved structure located deep within the DVR, surrounded by the N in all but the ventral position (Fig. 1). Depending on the posterior (AP8) to anterior (AP11) position, dorsal to the E is the M, hyperpallium densocellulare (HD), and hyperpallium apicale (HA). Ventral to the E is lateral striatum (LSt), globus pallidus (GP), and medial striatum (MSt) (Reiner et al. 2004). The E is a component of one of the two main pathways

**Entopallium, Fig. 1** Cross section through the pigeon brain demonstrating the location of the E (shaded gray). The following are the brain regions as defined by Reiner et al. (2004). *AI* arcopallium intermedium, *E* entopallium, *GP* globus pallidus, *HA* hyperpallium apicale, *HD*

hyperpallium densocellulare, *LSt* lateral striatum, *M* mesopallium, *MSt* medial striatum, *N* nidopallium, *NF* nidopallium frontale, *NI* nidopallium intermedium, *TPO* temporo-parieto-occipitalis

that transmit information to the telencephalon in the avian brain. The thalamofugal pathway projects from the retina to the nucleus opticus principalis thalami (OPT) and then to a region of the dorsal telencephalon known as the visual Wulst (HA and HD). The tectofugal pathway, on the other hand, projects from the retina to the optic tectum (TeO) and then bilaterally to the nucleus rotundus (Rt) and finally ipsilaterally to the E (Fig. 2; Krützfeldt and Wild 2005). The consensus from studies examining the projections from Rt to the E is that the projections are organized topographically along the anterior–posterior axis, such that neurons in the anterior Rt project to anterior E, while neurons in the posterior Rt project to posterior E.

The E can be divided into two main subregions, the core (Ec) and the peripheral belt (Ep), with Ep surrounding Ec (Karten and Hodos 1970). In the zebra finch, the outer boundary of E is

clearly defined; however, in the pigeon, the boundary appears intermittent. The cells in the two subregions can be differentiated on the basis of a number of characteristics, as well as their projection patterns. With respect to cell characteristics, Ec is populated mainly with medium-sized round cells with thick myelinated axons that are generally parvalbumin (PV) positive. In contrast, Ep neurons are characterized by smaller and longer cells with thin myelinated axons, very few of which are PV positive, the exception being the zebra finch, which has a greater number of PV-positive cells in area Ep.

With respect to afferent and efferent projections, the major projections from Ec are primarily directed to Ep and then onto Ep2 (Fig. 2), an ill-defined area immediately surrounding the Ep and that some consider similar to Ep (Krützfeldt and Wild 2005). For the current entry, Ep2 is considered to be coextensive with Ep. Much like the

E

**Entopallium, Fig. 2** The afferent and efferent projection patterns of the E. The E is part of the tectofugal pathway. Information flows from the retina to TeO and then to the Rt and from there in a topographical fashion to Ec. From Ec, information projects to Ep and then the rest of the avian pallium. Arrows in solid line represent major projection patterns, while dashed arrows represent minor projection patterns, with all arrow points indicating the direction of

the projection. Regions shaded in Rt and E represent the anterior, intermediate, and posterior divisions of each area. The following are the brain regions as defined by Reiner et al. (2004). AI arcopallium intermedium, Ec entopallium core, Ep entopallium peripheral belt, M mesopallium, NC nidopallium caudale, NF nidopallium frontale, NI nidopallium intermedium, Rt nucleus rotundus, TeO optic tectum

projections to the E from Rt, the projections from Ec to Ep, and from Ep to other pallial regions of the avian brain are also arranged in a topographical manner along the anterior–posterior axis, such that projections from the anterior portion of Ep are sent to nidopallium frontale (NF), projections from the intermediate regions of Ep to temporo-parieto-occipitalis (TPO), and projections from posterior regions of Ep to nidopallium intermedium (NI). Along with the major projections from Ep, there are minor projections from the posterior regions of Ec to arcopallium intermedium (AI) and nidopallium caudale (NC).

Although the majority of projections to the pallial regions of the avian brain originate from Ep, there are minor projections from Ec to the NF, TPO, and NI as well (Krützfeldt and Wild 2005). In the zebra finch and chickens, Ec also projects to the lateral striatum (LSt), and Ec may also have

reciprocal projections with the M in both the zebra finch and pigeon (Krützfeldt and Wild 2005).

## Functions of Entopallium: Lesion Studies

Hodos and his many colleagues extensively explored the functions of the E in a series of psychophysical discrimination studies conducted throughout the 1970s and 1980s (see Hodos et al. 1988 and references therein). Damage to the E causes a variety of visual impairments. In one study, birds were trained to discriminate between a blank uniform stimulus and stimuli with different spatial frequency gratings. After E lesions, the birds showed impairments in visual acuity, that is, elevated thresholds for detecting gratings. E lesions also cause elevated luminous intensity thresholds. Similarly, E lesions, especially medial

E lesions, cause elevated thresholds for detecting differences in the size of an annulus, a measure of low spatial frequency. Hodos and colleagues suggested that the medial E processes information about the low-spatial-frequency structure of stimuli, whereas the lateral E processes information about the high-spatial-frequency structure of stimuli.

Damage to the E also causes impairments beyond elevated psychophysical thresholds, such as in the processing of complex visual information. For example, Bessette and Hodos (1989) reported that pigeons with E damage show marked deficits in the ability to discriminate between different patterns (e.g., vertical vs. horizontal line or triangle with apex at top vs. triangle with apex at bottom) and intensities (two squares that differed in luminance) but not colors (green vs. yellow). Additionally, others have reported that E lesions cause impairments in the ability to discriminate between a number of different mirror-image and non-mirror-image stimuli that were matched on the basis of luminance. The most striking impairments after E lesions are in the ability to discriminate lateral mirror images, and this does not seem to be a function of difficulty, as the lateral-mirror-image discrimination was acquired preoperatively at the same rate as the other mirror-image and non-mirror-image discriminations.

Watanabe (1996 and references therein) conducted a series of studies in the 1990s examining the role of the E in the processing of ecologically relevant and ecologically irrelevant stimuli. Lesions of the E does not impair the ability to discriminate food items (corn, peas, buckwheat, and wheat) from nonfood items (stones, twigs, nuts, and yellow paper clips) but does impair the ability to discriminate these stimuli when they were randomly arranged into two groups (e.g., corn, peas, stones, and twigs vs. buckwheat, wheat, nuts, and yellow paper clips), a finding that likely reflects the fact that the randomly arranged discrimination is harder than the food versus nonfood discrimination. Similarly, E lesions impair the ability to discriminate between many exemplars of a triangle versus many exemplars of a line, but have little effect

on the ability to discriminate between one triangle and one line.

E lesions also cause an impairment in the ability to discriminate one pigeon from another pigeon, but do not impair the ability to discriminate one pigeon from another bird such as a quail. Although such a finding might reflect the fact that the E is important for discriminating members of one's own species from another, again it could also reflect task difficulty, with the pigeon versus pigeon discrimination more difficult and hence more sensitive to E lesions than the pigeon versus quail discrimination. Indeed, the effect of task difficulty was confirmed when in a follow-up study, Watanabe (1996) showed that E lesions also cause impairments in the ability to discriminate between a sparrow and a starling, but not between pigeons and other birds. Also related to task difficulty is the finding that E lesions do not impair the acquisition of color discrimination (yellow vs. green) but does impair subsequent reversals of the color discrimination.

In some of the aforementioned lesion studies, the impairments are correlated with the extent of damage to Ec, whereas in other studies what seems important is the total extent of the lesion to the E. As of yet, no firm functional differentiation has been uncovered for the core versus the belt regions. Some, however, report functional differences within different regions of the E as a whole. The earlier reported study by Hodos and colleagues, for example, proposed functional differences between the medial and lateral E with respect to the processing of low- and high-spatial frequency information. Nguyen et al. (2004) also report functional differentiation within the E. Birds were trained on a psychophysical procedure to perform either a pattern discrimination or motion discrimination, both with varying degrees of background noise superimposed upon the images. The authors uncovered a double dissociation, with birds with rostral E lesions impaired on the pattern discrimination and not the motion discrimination, whereas birds with caudal E lesions impaired on the motion discrimination and not the pattern discrimination. The findings of both pattern and motion impairments following lesions to the E suggest that it may serve functions similar to

the primate's extrastriate cortex, which houses areas responsible for both pattern perception (e.g., inferior temporal cortex) and motion perception (e.g., area MT).

### Functions of Entopallium: Electrophysiological Studies

Early studies reported that cells in the E display characteristics similar to those reported in extrastriate visual cortex of primates (see Colombo et al. 2001 and references therein). For example, compared to the receptive fields of neurons in visual Wulst and primate striate cortex, the receptive fields of neurons in the E and primate extrastriate cortex are generally large. Similarly, the receptive fields of cells in visual Wulst and striate cortex are retinotopically mapped, whereas those in the E and extrastriate cortex show little retinotopic mapping.

Beyond the small number of studies characterizing the basic properties of E neurons, however, few electrophysiological studies have been conducted. Those that have been conducted further add to the view that the E represents a higher-order visual processing region in the avian brain similar to the primate extrastriate cortex. Using a variety of differently shaped and colored stimuli that included pictures of pigeons, Scarf et al. (2016) reported that over 90% of E neurons are visually responsive and 20% show selective activity for one or more of the tested stimuli, numbers higher than any of the other three areas examined (nidopallium, arcopallium, and hippocampus) and numbers that are not only in line with extrastriate regions of the primate brain but are representative of what one might expect from a higher-order visual area. Some neurons in the E are also selective for the size, speed, or direction of stimulus movement, a trend thought to be associated with the large receptive fields found in the E. The findings of neurons responsive to shape and motion further add to the view that the E serves a similar function to the primate extrastriate cortex.

The E is also involved in memory for visual information. According to Johnston et al. (2017 and references therein), 70–85% of E neurons

display activity during the delay period of a delayed matching-to-sample task when the animals are required to remember visual information. Additionally, E neurons are more likely to display delay activity when the pigeons are completing the task at high (>75% correct) compared to low (<75% correct) performance levels. Johnston et al. (2017) also report that delay activity remained stable throughout the delay period. The finding of delay neurons, that encountering delay neurons is more likely when the animal is performing well as opposed to poorly, and the fact that delay activity remains stable throughout the delay period parallel the characteristics of memory cells found in the primate extrastriate cortex.

### Conclusion

The E is the pallial termination point of the tectofugal pathway. From the E, information is distributed throughout the rest of the avian brain. The E is primarily a visual structure and damage leads to impairments in visual acuity, brightness discrimination, size discrimination, as well as the ability to discriminate different shapes and naturalistic objects. Damage to the E also causes impairments in motion perception. There is little evidence at present to support a functional difference between the core and belt regions, although there is some evidence for functional differentiation along the medial and lateral extent of the E, and in particular between the rostral and caudal extent of the E, with the rostral area being more involved in pattern discrimination and the caudal area more involved in motion discrimination. The E may also play a role in visual memory and cognition. On the basis of projection patterns, the effects of lesions, and findings from electrophysiological studies, the E has functions similar to regions of the primate extrastriate cortex.

## Definition

The entorhinal cortex (EC), a brain region critical to memory processes, consists of six cortical layers located in the medial temporal lobe. Most contemporary subdivisions of the EC include a lateral and medial subfield, consistent with (1) the distribution of input fibers that this structure receives from the perirhinal and postrhinal/parahippocampal cortices (2) the distribution of its output projections onto the hippocampal formation (HF) and more recently

(3) functional differences observed in lesion and electrophysiological studies.

## Current Knowledge

### Brief Overview

The entorhinal cortex (EC), a brain region critical to memory processes, consists of six cortical layers located in the medial temporal lobe. After a series of preliminary naming conventions used in early histological reports, nomenclature shifted to emphasize the position of this structure with respect to the rhinal sulcus (Insausti et al. 1987; Witter et al. 1989). Over the course of a century of anatomical descriptions of the EC, as many as 23 subfields have been identified, depending on the criteria used to subdivide this structure (Insausti et al. 1987). Most contemporary parcellations have converged on defining lateral and medial subfields, consistent with (1) the distribution of input fibers that the EC receives from the perirhinal and postrhinal/parahippocampal cortices (Burwell and Amaral 1998), (2) the distribution of its output projections onto the hippocampal formation (HF) (Witter et al. 1989; Insausti et al. 1987), and more recently (3) functional differences observed in lesion and electrophysiological studies (reviewed in Knierim et al. 2014). Although the precise role of the EC in cognition remains obscure, results from clinical, histological, electrophysiological, and lesion studies point to its unique contributions within the system of brain regions subserving episodic memory in general, and spatial navigation in particular (Moser et al. 2008; Knierim et al. 2014).

### Structure

**Gross Anatomy.** The entorhinal cortex (EC) receives a diverse array of cortical and subcortical inputs and is bidirectionally connected with the hippocampal formation (HF) (Burwell and Amaral 1998; Insausti et al. 1987). Defining the anatomical boundaries of the EC poses a challenge due to the heterogeneity in cell type and organization, as well as the dense connectivity of the EC with adjacent regions. In order to mark the

boundaries of structurally and functionally distinct subregions, contemporary parcellations have taken into account both cytoarchitectonic appearance and distribution of input and output fibers across the rostrocaudal and mediolateral extents of the EC (Witter et al. 1989; Insausti et al. 1987).

**Inputs.** Although exact anatomical configurations differ across model species, structurally analogous connectivity patterns have been identified across rodents, bats, nonhuman primates, and humans. To date, some of the most extensively characterized connections arise from the rodent perirhinal and postrhinal cortices (perirhinal and parahippocampal cortices, in primates) (Canto et al. 2008; Burwell and Amaral 1998). In the rodent, perirhinal and postrhinal inputs largely terminate onto the superficial layers of the EC. While perirhinal projections preferentially target the lateral entorhinal area (LEA) of the EC, postrhinal projections primarily innervate the medial entorhinal area (MEA). Although the primate EC has been subdivided into approximately five areas, a homologous gradient of preferential targeting exists as perirhinal inputs predominantly innervate rostrolateral regions, while parahippocampal projections primarily impinge on caudomedial areas (Insausti et al. 1987). Several subcortical regions, such as the amygdala, the basal forebrain, and the claustrum, have also been found to reciprocally connect to various portions of the EC (Canto et al. 2008; Witter et al. 1989).

**Outputs.** The main output of the EC consists of the “perforant path.” Originally described by Ramón y Cajal, this dense bundle of fibers arises from the cells in the superficial layers of the EC and “perforates” through the subiculum to innervate each of the major subfields of the hippocampal formation (Canto et al. 2008). The distribution of perforant path terminals depends on the origin of the fibers in the EC. For instance, LEA projections preferentially impinge on the outer third of the molecular layer of the dentate gyrus, while projections from the MEA primarily innervate the middle third. Early anatomists used this topographic distribution of perforant path terminals onto the dentate gyrus as a main criterion to

mark a distinction between the lateral and medial subfields of the EC (Witter et al. 1989).

## Theories of Function

**Histological, clinical, and lesion studies.** Early functional hypotheses of the EC were prompted by reports of neural degeneration of this structure in patients diagnosed with Alzheimer's disease (AD), a neural pathology characterized by increasingly severe memory deficits. Braak and Braak (1991) examined the extent of accumulation of neurotoxic protein aggregates in the brains of patients with AD. Results revealed that neurofibrillary tangle deposits follow a characteristic spatiotemporal spread that corresponds to disease progression. Specifically, toxic deposits were consistently found in transition zones between the EC and the neocortex during early stages of the disease. Brains of patients with intermediate disease pathology exhibited dense neurotoxicity throughout the EC, followed by a gradual encroachment of neurofibrillary tangles into the HF and neocortex in later stages of pathology. These findings suggested that the etiology of this disease, and the related memory impairments, could be traced to early entorhinal pathology.

Controlled lesion studies in nonhuman primates have facilitated further examination of the role of the EC in memory. Bilateral removal of the EC has been carried out in monkeys who subsequently performed a series of tasks designed (1) to assess their ability to learn associations between pairs of objects and (2) to infer relationships between objects whose relationships were not explicitly defined during the learning phase. Although monkeys with EC lesions took longer to learn the original associations than the intact monkeys, they could reliably produce appropriate behavioral responses indicating their recognition of the relationship between paired objects. However, monkeys with EC lesions were notably unable to flexibly use previously learned associations to make inferences regarding the reward value of the familiar objects in novel configurations. This striking observation led investigators to posit that while structures other than the EC

might subserve acquisition of associations between objects, the EC might critically contribute to supporting the flexible use of an established relational framework to guide behavior (Buckmaster et al. 2004).

**Electrophysiological studies.** Although a wide array of cortical and subcortical brain regions modulate electrical activity patterns in the EC, investigators have largely based functional hypotheses on the distribution of inputs arriving from the perirhinal and postrhinal/parahippocampal cortices. A prominent theory in the field posits that perirhinal and postrhinal/parahippocampal inputs into the EC constitute largely parallel information streams, providing preferentially multimodal object information to the LEA and visuospatial information to the MEA. Investigators have hypothesized that this apparent information segregation allows the subfields of the EC to independently process information regarding the *content* of an experience (multisensory object information) and the *contextual* circumstances (visuospatial information) that scaffold and facilitate an experience. According to this classical view, the LEA and MEA would in turn further process and ultimately route this information to the hippocampus, where content and context information could be combined to encode an "episode" (reviewed in Knierim et al. 2014).

Leaders in the field are careful to note that this functional model, in its current formulation, fails to capture the plurality of inputs that the EC receives, including feedback from the hippocampus itself (see Gross Anatomy). Moreover, the reciprocal connectivity between the LEA and MEA have led some to suggest that information regarding the content and the context of an experience is integrated to some extent prior to being transmitted to the HF (Burwell and Amaral 1998; Canto et al. 2008; Knierim et al. 2014). Extracellular recordings of the electrical activity of neurons in the EC have proved invaluable in parsing through these hypotheses and probing the function of this structure and the contributions of each of its subfields to episodic memory and spatial cognition (Moser et al. 2008; Knierim et al. 2014).

**Medial entorhinal area (MEA).** Structurally, MEA cell types vary widely according to shape and connectivity. Functional differences are also apparent, as patterns of electrical activity are robustly correlated to distinct variables such as the animal's head direction or the physical borders of an environment. More recently, functionally defined "grid" cells were found to selectively increase their activity in a pattern that corresponds to the vertices of tessellated triangles (Hafting et al. 2005). The electrical activity of grid cells thus "tiles" space as an animal traverses an environment (Hafting et al. 2005). The presence of neurons tuned to head direction, borders, and a grid-like patterning of space has fueled influential hypotheses regarding the role of the MEA (and the hippocampus) in spatial cognition (Moser et al. 2008; Knierim et al. 2014). Particularly, several key investigators proposed that this network of MEA cells could integrate visuospatial and vestibular information in order to continually update the animal's position over time with respect to the boundaries of an environment. These theoretical insights were recognized with the 2014 Nobel Prize, for their potential to constitute a neural substrate of spatial navigation and cognition (Moser et al. 2008, Knierim et al. 2014).

**Lateral entorhinal area.** While less is known regarding the neural correlates of behavior in the LEA, some studies provide evidence to suggest that the electrical activity of a subset of cells in this area might contain information for the identities or locations of objects experienced within a given spatial environment. Tsao et al. (2013) recorded the LEA as rats explored an environment that contained an object in a fixed location. Consistent with previous findings, some cells responded only when the rat sampled a given object, while other cells consistently increased their activity when the rats traveled over locations at fixed distances away from particular objects. When the object was relocated within the same environment, another subset of cells selectively increased their activity as the rat traveled over the space where the object had been *previously* located. Investigators then found that as the object was moved to different locations along the environment and then subsequently removed, the

activity of these cells tracked the history of locations that the object had occupied, but not the identity of the object itself (Knierim et al. 2014; Tsao et al. 2013). Importantly, the integrity of the response fields of LEA neurons decayed once the rats encountered the familiar object in a novel context. These findings suggest that the LEA does encode some information about the contextual scaffolding of an experience, presenting subtle challenges to the classical view of information processing in the LEA (Knierim et al. 2014).

## Summary and Future Directions

Rigorous anatomical characterization has ultimately facilitated a framework in which to interpret results from clinical, lesion, and electrophysiological studies in animal models, in an ongoing effort to elucidate the contributions of the EC to memory processes. A century of study through this diverse repertoire of approaches provides some evidence to suggest that this structure critically contributes to organizing relationships between stimuli and the contexts in which experiences take place. Moving forward, behavioral paradigms designed to assess previously unexplored cortical and subcortical influence on information processing in the EC might facilitate a richer understanding of the role of this brain region in cognition and behavior.

## Definition

External factors that affect humans or any other life form

Before the nineteenth century, the effects of the environment on an organism were not well studied. Wilhelm Johannsen, a Danish botanist, first found differences in observable physical properties of genetically identical bean plants. He coined genetic content as “genotype” and observable properties as “phenotype.” He concluded from his experiments that these variations in phenotypes are caused by environmental factors (or environmental influences; Johannsen 1911).

Genotype is not the sole factor that decides the phenotype of any organism; there are several environmental influences which possibly modify them. Researchers are particularly interested in studying effects of environmental influences on development, growth, and health over long periods of time, as well as in humans and other animal species. Understanding of this unpredictable interplay between environment and genetics may provide insight of how a person may differ from its predefined genetic makeup.

Gene, a small part of our genome (entire genetic content), is the smallest functionally heritable unit of the entire genetic content of any organism. Each gene consists of two variant forms known as alleles; at a given loci (location of gene on chromosome), two alleles are present, one contributed by the father and one by the mother. These alleles encode a specific protein that is responsible for providing a characteristic

phenotype to an individual. The combination of these two alleles will produce different phenotypic characteristics (Lewis 2002).

The environment includes everything that surrounds us and can possibly affect us in one way or another. It includes common modifiable factors like lifestyle, dietary habits, and physical activity and other non-modifiable factors like temperature, humidity, season, migration, demographics, etc. In humans and many other organisms, these environmental factors can influence the gene expression, therefore significantly affecting the phenotype with time. Growth and developmental studies in relation to various environmental influences like temperature, high altitude, seasonality, migration, and activity are already established (Schell et al. 2009). Regulation by the environment is a normal component of development and growth for all the organisms (Gilbert 2014).

### Environmental Influences During Embryo Development

Both genotype and environmental influences work synergistically to produce a phenotype. One common example is linear growth (height or length). An individual may carry a genotype of normal growth, but availability/consumption of a proper growth-promoting diet will affect the phenotype by means of metabolism and changed pattern of hormone production in the body. Tall parents can be expected to have offspring with good/tall stature. This can be solely attributed to the fact that they carry “genes for good height.” However, if offspring do not receive proper nutrition and diet during their growth years, their growth can be stunted due to the absence of proper nutrition required to express that growth genotype.

The sensitivity of animal growth and development to social and environmental conditions was established early in the modern era of growth studies (Schell et al. 2009). Environmental influences are well-known to affect development before birth; this “extent of influence” is so strong that it contributes toward fetal developmental

syndromes and congenital defects. Environmental influences affect the development of the embryo/fetus in two different ways. Some intrinsic maternal environmental features like age and external environmental features like nutritional deficiency, certain diseases, smoking, alcohol consumption, drugs, and emotional stress during pregnancy can increase the risk of miscarriage, stillbirth, premature delivery, improper development of the newborn, congenital defects, etc. These external (i.e., physical and chemical) agents with the ability to produce defects in newborns are collectively known as teratogens.

Commonly known teratogens like azaserine, alcohol, glyphosate, thalidomide, thiadiazole, triazene, and 6-aminonicotinamide are known to be teratogenic to both humans and several lab animals (Murphy et al. 1957). These teratogens mediate effect by different means. Glyphosate, thalidomide, and several other teratogens are known to mediate developmental defects in animal embryo through chromosomal abnormalities (Soukup et al. 1967). Also some are reported to block pathways responsible for developments of limbs as well (Tantibanchachai and Yang 2014).

Thalidomide was a commonly used drug in the USA in the 1950s; it was known to be one of the safest drugs available in the market. Studies confirmed that it had no side effects on healthy adults and their gene expression. However, when it was created, its teratogenic effect on fetuses was unknown. Research studies led by William McBride and Widukind Lenz reported that thalidomide was a potent teratogen. These agents are known to exert their adverse effect by changing the expression of significant genes. They are also known to exert their effect by altering the synthesis of important hormones and any other significant metabolite in the body (Jürgen and Rüther 2008).

Similarly, severe poisoning caused by mercury in Minamata, Japan, proved that, during development, exposure to undesired agents can affect fetal development. It is very well established that mercury enters into the body from fish, which is the main diet in Japan (Schell et al. 2009). Fetuses and newborns are particularly susceptible to certain environmental toxins.

## Environmental Pollution Influence on Humans and Other Living Organisms

Although fetuses, neonates, and young children are more at risk from environmental pollutants, adults are also affected by these toxins. Exposure of environmental toxins like heavy metals (lead, mercury, arsenic, etc.), toxic chemicals (several pesticides, dioxins, phenolic compounds, etc.), and many other compounds are known to increase the risk of developing human diseases like cancer, disorders of nervous system, and several other diseases/disorders as well (Bolger et al. 2002). An American community-based study showed a strong association of environmental pollutants exposure to sexual maturation, obesity, and disturbed thyroid function, which are known to severely affect growth and maturation of adults (Schell et al. 2009). One of the very recent and notable examples in this context is urban air pollution; it is so severe in some cities in developing and a few developed countries that the majority of young children and elderly adults are suffering from various respiratory disorders like asthma and other chronic airway diseases (Jiang et al. 2016). Animals are not spared from these toxins. A British study found feminization of male fishes due to industrial discharge in rivers. It is reported that certain toxins known as reproductive toxins were responsible for this sex reversal (Gross-Sorokin et al. 2006).

All living species are now facing a different kind of challenge due to artificial/man-made environments and its influence on them. It is very well established that this artificial environment that mainly includes pollution affects all living organisms. Current research is looking into the role and other aspects of the artificial, human-made environment full of pollutants and how it influences human, animal growth, and development.

## Behavior and Environmental Influences

Behavior is an important attribute of an organism; it is a response to the external environment. The study of how behavior is predetermined or influenced by the environment has long been a popular topic of research and debate among researchers and intellectuals.

Studying effects of environmental influences on behavior is difficult as each person varies genetically and thrives in different environments. However, studies on genetically identical twins or monozygotic twins provide a valuable way of understanding how the environment can affect genetically similar individuals differently. Identical twins are produced from a single cleavage of zygote (formed after fusion of female egg by male sperm), having similar genotype (100% same genes). Studies comparing identical twins reveal how environmental influences affect phenotypes among them. It is very commonly known that identical twins have different fingerprints as fingerprint patterns are affected by the environment (Choi and Kim 2007).

Although twins are known to have similar visible traits, behavior is one of the factors that is greatly influenced by the environment as well. Twins raised in the same environment are known to have strikingly different behavioral traits like personality, ability, preferences, etc. A study in 1960 indicated that twins can have different behavior right from the birth, which can be affected by factors like birth sequence and birth weight. Moreover, common social factors like parental and peer influence are known to shape behavior differently even for genetically identical individuals (Brown et al. 1967).

Proof of genetic background of behavior are limited, but factors like personality traits, IQ, social traits, and even alcoholism are strongly linked to genetic inheritance. Research fails to identify specific genes that may directly link to specific behavior, making it difficult to understand the relation. Besides, substantial evidence is present to link behavior to the environmental influences, and scientists consistently believe that non-shared environmental factors (environmental factors not shared with other children of the same family) have more impact on the behavior differences than shared factors (Brown et al. 1967).

## Environmental Influence on Animals

Light, temperature, and resource availability are the most commonly known external environmental factors. Their influence on phenotypic

development is very well established in animals ranging from insects to reptiles to mammals.

A recent study reported that environmental influence possibly affects cognition in lizard species. Temperature was found to influence brain performance and anatomical structure in young lizard (*Pogona vitticeps*). Lizards incubated at colder temperature were found to be quick social learner and performed their task quickly as compared to lizards incubated at higher temperature (Siviter et al. 2017). These findings are further supported by another study by Pike et al. (2018): they found that short-term brain plasticity (overall size and development of certain brain region) is influenced by environmental factors. Their research suggested that fishes developed under low-light/visually restricted condition have significantly smaller optical region besides significantly larger olfactory bulbs as compared with fishes from normal visual condition. Their brain preferentially uses olfactory chemoreception over visual perception.

Influence of temperature on phenotypic development is very well established in Himalayan rabbit species. Temperature strongly influences expression of skin pigment producing gene in these animals. C gene is pigments-producing gene in the rabbit body parts like eyes, fur, skin, etc. Its expression is temperature dependent. This gene is known to be inactive above 35 °C; it is highly expressive between the temperature of 15 °C and 25 °C. This temperature-regulated expression of C gene produces distinctive coat patterns among rabbits. In warm body parts, the gene is inactive and produces no pigments. Meanwhile, in other body parts like the ears, nose, and feet where the temperature is below 35 °C, it produces black pigment, making these parts darker than other body parts (Sturtevant 1913).

Optimal light is also known to affect gene expression status in butterflies, affecting their growth and development. Thomas Hunt Morgan studied caterpillars under different lights in 1917. He kept caterpillars under controlled light conditions (red, green, blue light), and some caterpillars were kept in the dark. These caterpillars exhibited drastic differences in wings. Red light exposure resulted in wings with intense color, and green light exposure resulted in dusky wings, while

darkness and blue light produced pale wings (Morgan 1917).

Whereas sex of most animals is determined by genetic factors, in some animals like all crocodile species and many species of turtles, sex is determined by temperature. In these species, temperature plays a pivotal role during certain critical developmental stage in sex determination. A common example of such temperature-dependent sex determination is red-eared slider turtles (*Trachemys scripta elegans*). If the nest temperature is below 28 °C, all the hatchings will be males. If the nest temperature is above 31 °C, all will be females. Temperatures in-between will produce offspring of both sex with equal probability (Shoemaker and Crews 2009).

Many insect species have developed strategies to properly deal with adverse environmental condition known as diapause, also known as animal dormancy. It involves suspension of development at any phase of life cycle (embryo, larva, pupa, or adult) until favorable conditions are available for supporting growth (Gilbert 2014).

These examples indicate strong environmental influences on gene expression in animal species as well. However, it is important to keep in mind that there is a very complex interaction between genes and environment that defines phenotype and who we are.

## Environmental Influences and Human Diseases

Environmental influences have great impact on our health. Lifestyle diseases are “group of diseases” that are linked to “long-term habits.” All the major lifestyle diseases (diabetes, heart diseases, cancer, asthma, obesity, and many other diseases) have a very strong environmental background (Sharma and Majumdar 2009). A person may carry a disease-causing gene or set of genes (family history of a disease), but chances of development of that disease will significantly depend on the environment. Individuals with a family history of lung cancer are less likely to develop the disease if they avoid any kind of tobacco use. Similarly, individuals with a

family background of diabetes or heart disease are less likely to develop them if their dietary habits (healthy food) and lifestyle (physical activity) are adjusted according with disease risk. People living in heavily polluted urban industrial areas will suffer more from asthma or any other respiratory disease as compared to people living in areas with comparatively less or near to nil air pollution. Similarly, lifestyle changes of diet and activity in recent times (high-calorie food and fast-food consumption and lack of proper exercise) have been responsible for a very rapid growth in obesity in developed and developing countries over the past several decades (Brantley et al. 2005). Moreover, an individual raised in a disturbed family environment is also similarly at higher risk for developing mental disorders like schizophrenia, bipolar disorder, etc. (Brown et al. 1967).

It is also important to understand that all these diseases involve controllable risk factors (lifestyle or environment) and uncontrollable risk factors (genetic factors) that cannot be changed. The interplay of both will dictate the chances of developing such diseases in any person.

## Conclusion

We wonder about the factors that affect our personality and characters. Plenty of researchers around the world are studying and debating the nature (inherited genotype or set of genes) versus nurture (environment) for a very long time. Every individual has their own unique environment that guides their overall development. Both of these factors are equally important, and either one of them cannot be downplayed in determining a person's phenotype. However, most but not all features involve environmental modification of a phenotype. Some characteristics (e.g., eye color and appearance) have higher genetic weightage on their expression and are not affected by the environmental influence. After considering all the facts, it can be safely said that environment is like a mold that will always dictate how an organism shapes itself within it.

[DNA methylation](#); [Epigenetic modification](#)

## Definition

Epigenesis is a mechanism by which modifications are introduced during embryo development which does not affect the nucleotide sequence but alters the expression of genes (Russo et al. 1996). These epigenetic modifications are inherited by mitosis and can cause short-term or long-term changes in gene expression. Epigenome is the term for the epigenetic modifications to the genome of an organism. Epigenetics is required for embryo development and cell differentiation and also facilitates transcription of genes and silencing of genes. Environmental conditions also influence the epigenetic pattern, and thereby the expression pattern of genes such as adverse environmental conditions like inadequate healthcare and poor nutrition can introduce long-lasting effects in the offspring including predisposition of diseases like diabetes and heart diseases. Epigenetic modifications in the offspring are also likely to undergo trans-generational inheritance (Gong et al. 2010). Mechanisms involved in epigenetic modifications are DNA methylation, histone modifications, and small RNAs.

## DNA Methylation

DNA methylation is catalyzed by the DNA methyltransferases which are the class of enzymes involved in covalent attachment of methyl (CH<sub>3</sub>) group to the 5' position of the cytosine (5'-methylcytosine) in the dinucleotide sequence CpG (Bird 2002). Mostly, the CpG islands are present in the promoter region of the genes, and hypermethylation of the promoter region causes gene silencing (Fig. 1).

There are four types of DNA methyltransferases:

1. DNA methyltransferase 1 (DNMT1)
2. DNA methyltransferase 2 (DNMT2)
3. DNA methyltransferase 3a (DNMT3a)
4. DNA methyltransferase 3b (DNMT3b)

DNMT3a and DNMT3b are the examples of de novo methyltransferases that introduce new

**Epigenesis, Fig 1** Mechanism of methylation of the cytosine residue by DNA methyl transferase enzyme (DNMT)

**Epigenesis, Fig 2** De novo methylation and maintenance methylation of the DNA sequence

pattern of methylation in the genome particularly during early embryo development, while DNMT1 is an example of maintenance methyltransferases which after cell division maintain the methylation pattern (already introduced by the de novo methyltransferases in the parental strand) in the newly synthesized strand from the parental strand (Xu et al. 2010). DNMT2 is a putative methyltransferase with no evident activity reported (Fig. 2).

Different processes by which methylation of CpG island ensures silencing of the gene expression are unavailability of promoter region to the transcription initiation complexes, RNA polymerase inhibition, and accessibility of transcriptional repressor complexes (Murr 2010).

Addition of methyl group to the DNA changes the topological structure of it and provides binding site or domain for protein binding; for example, methyl-CpG-binding proteins (such as MBD1, MBD2, MBD3, MBD4, and MeCP2) bind to CpGs through methyl-CpG binding domains (MBD). Binding of MBPs further recruits other proteins such as DNMT1, histone deacetylases HDAC1 and HDAC2, human H3K9

methyltransferase (Suv39 h1), and heterochromatin protein 1 (HP1) (Fuks et al. 2003; Sarraf and Stancheva 2004; Stewart et al. 2005) which alter gene expression by changing chromatin structure that leads to heterochromatin state or silenced state.

DNA demethylation process is also as important as DNA methylation and involves unsuppressing the expression of the gene by removing the methyl groups from the DNA. DNA demethylation can be performed by the following two mechanisms:

**Passive demethylation:** Passive methylation occurs when DNMT1 enzyme is inhibited which causes no maintenance of the methylation pattern to the newly synthesized strand during replication.

**Active demethylation:** In active demethylation, methyl groups are either removed directly from the methylated DNA or may involve deamination or oxidation of the methyl group followed by removal by glycosylase enzyme (involved in base excision repair pathway). Active methylation is not dependent on replication.

## Important Roles of DNA Methylation

- (i) Differential DNA methylation of parental alleles which are known as differential methylated regions (DMRs) causes allele-specific expression of imprinted loci during development (Li et al. 1993).
- (ii) Chromosomal structural integrity maintenance (Chen et al. 1998).
- (iii) In defense of genome from parasitic retrotransposons (Yoder et al. 1997).

## Histone Modifications

Chromatin is composed of nucleosomes which package the long DNA molecule into compact structure with the help of basic proteins known as histones. Each nucleosome is made up of 146 base pair of DNA wrapped around histone octamer which is comprised of four subunits (H2A, H2B, H3, H4) in the core, and H1 subunit helps in the packaging of the nucleosomes (Luger et al. 1997). Histone octamer also possesses an unstructured N-terminal tail (apart from the core unit) which is subjected to different types of covalent modifications like methylation, acetylation, phosphorylation, biotinylation, sumoylation, ubiquitination, and proline isomerization in mainly four amino acid residues such as lysine, arginine, tyrosine, and serine.

Histone modification is a posttranslational modification and mainly associated with the gene expression regulation. Two major type of histone modification that regulates gene expression are methylation and acetylation of lysine residue in histone 3. Histone acetyl transferases (HATs) catalyze the transfer of acetyl group from acetyl coenzyme A to the histones, while histone deacetylase (HDACs) are the enzymes involved in the removal of acetyl groups from the histone (Fig. 3). Acetyl group is negatively charged and by binding with the lysine residue in the histone neutralizes the charge of the histone which further affects affinity with the negatively charged DNA molecule. This results in opening of the structure (euchromatin state) such that access of the transcription factors for gene activation becomes easy

and promotes gene transcription. Acetylation of H3K9 (**H3K9ac**) is an example of histone modifications associated with the activation of the gene expression. Likewise, histone methyltransferases (HMTs) catalyze the transfer of methyl group from S-adenosylmethionine (SAM) to histone. Methylation of histone (particularly at 9th and 27th lysine residue of histone 3) increases the affinity of the negatively charged DNA to the histone as methyl group is positively charged and results in the more compact form of nucleosome known as heterochromatin state which causes repression of gene expression. H3K9 trimethylation (**H3K27me3** and **H3K9me3**) is an example of gene silencing due to histone methylation. However, tri-methylation of H3K4 (**H3K4me3**) is associated with the activation of the gene expression (Davie 1998).

The histone modifications recruit DNA methylation enzymes, while DNA methylation recruits histone modification enzymes; thus, there is a cross talk between the epigenetic reprogramming mechanisms which is necessary for the controlled regulation of the gene expression.

## Noncoding RNAs

Noncoding RNAs are the molecules that are not translated into protein. They can be divided into short ncRNAs and long ncRNAs. Short ncRNAs can be further classified into miRNA, siRNA, and piRNA. Noncoding RNAs are reported to be involved in regulating gene expression by epigenetic modifications like DNA methylation, gene silencing, heterochromatin formation, etc.

- (i) **Short ncRNAs:** Short noncoding RNAs can be classified into three types:

**MicroRNAs (miRNAs):** MicroRNAs cleave or degrade target messenger RNA by binding to it via complementary sequence. Example of miRNA genes associated with the epigenetic-based regulation is mir-127 and mir-136 which regulate expression of Rtl1 protein essential for placenta formation in mice.

**Epigenesis, Fig. 3** Histone modifications in the presence of histone deacetylase (HDAC) and histone acetylase (HAT) enzymes.

**Short interfering RNAs (siRNAs):** It regulates posttranscriptional gene silencing by degradation of target mRNA molecule. It also promotes H3K9 methylation and heterochromatin formation by binding to the RNA-induced transcriptional silencing (RITS) complex.

**Piwi-interacting RNAs (piRNAs):** They interact with the piwi class of proteins and are involved in the suppression of transposon activity in cells by targeting and cleaving transposons.

- (ii) **Long ncRNAs:** The major group of noncoding RNA transcripts belongs to long ncRNA class. They are found to be associated with chromatin remodeling, posttranscriptional regulation, transcriptional regulation, etc. An example of the role of lncRNAs in epigenetic is X-chromosome inactivation (XCI). X-chromosome inactivation involves two lncRNAs, i.e., X-inactive-specific transcript gene (Xist) and antisense transcript of Xist known as Tsix which is a negative regulator of Xist.

## Methods to Determine Methylation Status of the Genome

There are three methods developed for DNA methylation detection:

- (i) **Bisulfite genomic sequencing:** It is based on chemical modification of the DNA sequence with bisulfite which involves conversion of cytosine residue to the uracil residue, but the 5-methylcytosine residues in the dinucleotide CpG remain unaffected. When PCR is performed on the bisulfite-treated DNA segment, non-methylated cytosine residues will convert to thymidine, while 5-methylcytosine residues will be cytosine only. Methylation pattern can be detected by direct sequencing of the PCR product. This method is used to determine methylation pattern at specific loci and can differentiate between single nucleotide polymorphism (thymidine and cytosine).
- (ii) **Methylation-sensitive restriction endonucleases:** This method is based on utilizing methylation-sensitive restriction enzymes like *HpaII* and *MspI*. Both *HpaII* and *MspI* recognize the sequence CCGG and are isoschizomer. This method identifies the methylation pattern in the DNA sequence either by enriching methylated region or by enriching non-methylated region.
- (iii) **Methylated DNA immunoprecipitation:** It is an affinity-based isolation method. In this method, genomic DNA is fragmented by sonication followed by immunoprecipitation with antibodies specific to 5-methylcytidine. The fragments of DNA bound with the antibody complex are then purified and used for identification of locus-specific (PCR) or genome-wide methylation pattern in the genomic DNA. This method is very rapid and efficient.

## Epigenetic Reprogramming During Embryo Development

Epigenetic reprogramming during embryo development is a bimodal DNA methylation pattern that occurs in two phases:

- (i) During the formation of the primordial germ cells (PGCs)
- (ii) During early embryo development soon after fertilization

These two events reprogram the epigenetic landscape to a basal level; i.e., demethylation and then remethylation occur on the basis of the differentiation of the lineages such that the PGCs differentiate into germ cells (sperm and eggs) and inner cell mass (ICM) of the early embryo differentiates into all the other cell types of the organism (Fig. 4).

Primordial germ cells are terminally differentiated cells that carry all the information necessary for the embryo development after fertilization. There is difference in the paternal and maternal genome due to differential expression of the paternal and maternal alleles of imprinted genes known

**Epigenesis, Fig 4** Epigenetic gene regulation during embryonic development

as genomic imprinting during development (Kobayashi et al. 2013).

Primordial germ cells are derived from epiblast cells (day 7.5) and migrate to germinal ridge (day 11.5) where differentiation of PGCs to sperm or egg occurs. PGCs are highly methylated when they enter germinal ridge and from day 11.5 to 12.5 undergo global erasure of DNA methylation in the genome including in imprinted genes as well. This is an example of active demethylation. However, it is global demethylation, but some regions of the genome avoid demethylation. Following demethylation, the de novo remethylation of PGCs of both sperm and egg initiates by day 16.5 when gametogenesis commences and ends on day 18.5 in male and before ovulation in maturing oocyte in females. Now both gametes are highly methylated and mature for fertilization event.

Second round of epigenetic reprogramming occurs between fertilization and blastocyst stage. After fertilization, paternally inherited genome undergoes rapid active demethylation within the first cycle of fertilization, while maternally inherited genome undergoes gradual passive demethylation (Smith et al. 2012). Erasure of DNA methylation pattern in the newly formed zygote continues till the end of blastocyst stage, but this demethylation does not affect imprinted gene methylation pattern. After implantation, de novo methylation of the embryo starts which

coincides with the differentiation of the embryo into the inner cell mass (ICM) and trophectoderm (TE). The inner cell mass (ICM) is hyper-methylated which forms all the tissue types, while the trophectoderm (TE) is under-methylated which is involved in placenta formation. On day 7, highly methylated PGCs arise from the extra-embryonic mesoderm of the developing embryo from the ICM.

## Reprogramming of Somatic Cell Nucleus

Somatic cell nuclear transfer (SCNT) is a nuclear cloning technique which involves transfer of somatic cell nucleus into the cytoplasm of the enucleated oocyte (Wilmut et al. 1997). The nucleus of the egg cell is removed through the process known as deprogramming of the egg cell. Somatic cell nucleus is then inserted into the enucleated egg cell which further results in the fusion of these two cells. The somatic cell nucleus inside the egg cell undergoes reprogramming due to the cytoplasmic factors of the egg cell. Dedifferentiation of the somatic cell nucleus results in the formation of new zygote; however, only 5% of the cloned embryos survive during development. The low rate of survival of the cloned embryos as compared to the fertilized embryos is because of the incomplete demethylation of the embryo before implantation and insufficient de novo

remethylation of the developing embryo. Abnormal epigenetic reprogramming results in improper methylation of some important genes (like Oct4, imprinted gene) which are essential for embryonic development. SCNT has potential importance in therapeutic cloning and reproductive cloning.

## Conclusion

Epigenetic reprogramming is the modification in the DNA such that it does not alter the sequence of the DNA fragment. Histone modification and DNA methylation are well studied and important mechanisms by which epigenetic regulation of gene expression is performed. Epigenetic reprogramming is well studied during embryo development and has essential role in embryo development as many diseases have been encountered in the last decades due to abnormality in the epigenetic reprogramming during embryo development. Understanding the exact mechanism and cross talk between different epigenetic mechanisms will provide new platform to identify many unidentified facts about genetics and developmental biology.

## Introduction

From antiquity, memory has fascinated intellectuals such as philosophers, artists, mathematicians, and more recently psychologists and neuroscientists. The definition of memory itself has evolved through time. The twentieth century has specifically impacted the study of memory. Under the influence of eminent scientists such as Bartlett (1886–1969), memory was no longer considered as a passive trace in the brain, but instead as an active process involving the reconstruction of previously encoded features. Human memory was divided into sensory memory (very short-term memory receiving perceptual and sensitive information from environment), short-term memory (temporary storage of information), and long-term memory (long-term storage of information). It is only during the second part of the twentieth century that long-term memory was divided in several types based on its different functions. Two broad long-term memory systems differing according to their accessibility to conscious recall (i.e., the capacity to retrieve information previously encoded) were described: the non-declarative and the declarative systems. Non-declarative memories, also called implicit or procedural memories (e.g., memory of habits, skills...), are characterized by an unconscious

processing of information (e.g., cycling does not need a conscious access of previously learned motor memories). On the contrary, declarative memories (or explicit memory) are characterized by the conscious recollection of facts and events. These declarative memories are in turn divided into two forms, semantic knowledge or labels about the world (e.g., Paris is the capital of France) and episodic memories or experiences (e.g., what I wore and how I felt last time I went to Paris), a distinction first made by Tulving (1972, 1983).

Episodic memory is the capacity to travel mentally back in one's personal past. Both episodic and semantic memories imply bringing memories into conscious awareness; however consensus in the scientific community states that they differ in terms of the nature of information they convey (Tulving 1972, 1983). Semantic memory refers to general knowledge of the world (e.g., Paris is the capital of France), while episodic memory refers to the memory of *personally experienced* past events (e.g., a memory of a poignant moment spent with friends). Episodic memory involves contextual information pertaining to the previously experienced event (i.e., temporal and spatial information). The phenomenological aspects of episodic memory have been defined by Tulving (1972, 1983): namely, the personal and conscious recollection of an event that occurred in the personal past (i.e., I am aware that I am remembering a specific event from my past, and I know that I live in the present and that I can recall memories from *my* past or anticipate future events). One crucial phenomenological element is called *autonoetic* consciousness (i.e., self-knowing) and another is *chronesthesia* (an awareness of the passage of time). Together they build personal identity by accessing autobiographical information about how the self moves and changes through time while maintaining identity and integrity (e.g., *I* am different from someone else, and *my* memories belong to my *personal* past). These phenomenological elements make episodic memory a very special type of memory precisely because it is rooted in *self* (i.e., one's identity), in *time* (i.e., the past), and in *consciousness* (i.e., being aware of the external environment

and of one's internal state and how these make and maintain changes in the self through time). This definition of episodic memory in terms of consciousness has long led authors' claim that episodic memory is unique to humans.

The distinction between episodic and semantic memory arose from neuropsychological studies of amnesic patients presenting an impairment of episodic recall while semantic knowledge was preserved. In these studies, patients were not able to create new episodic memories and to retrieve episodic memories from several years before their brain damage. That is, the owner of a semantic memory will *know* one fact he encoded in his semantic memory but will not be able to recall any contextual information present at the moment of encoding (e.g., temporal or spatial information). At the opposite, the owner of an episodic memory will *remember* this memory by recollecting the specific features present when the memory was formed (e.g., perceptual, sensitive, emotional, cognitive information). From a methodological point of view, episodic memories are created after a single presentation of an event. Multiple presentations of such an event would lead to semantic information processing. The crucial notion hidden behind these statements is the "expectation of being asked." Indeed, it is now debated whether animals should be asked unexpected questions in order to eliminate rule-based (i.e., semantic) explanation of the behavior to investigate episodic cognition in animals.

Episodic and semantic memories would represent two parallel subsystems where episodic memory is embedded within semantic memory. According to Tulving (1983, p. 66), the two systems "can operate independently of the other, although not necessarily as efficiently as it could with the support of the other intact system." The two systems seem to share cerebral structures, such as the hippocampus (Suzuki and Clayton 2000). That is, even if their functioning is different, episodic and semantic subsystems interact and are part of the same memory organization.

Some researchers argue that remembering the temporal component of an episodic memory may involve retrieving contextual information instead of a specific timing, for instance, recalling which

objects were present when the memory was encoded (Eacott and Norman 2004). The specific type of memory in charge of recalling contextual features that were present when the episodic memory was formed is called source memory (Johnson et al. 1993). Episodic recollection is being triggered by contextual information; source memory tasks are designed to study episodic memory.

Episodic memory is the retrospective part of mental time travel which corresponds to the ability of re-experiencing of personal past event (remembering the past), and episodic future thinking is the pre-experiencing of future events (imagining the future) which involves the prospective nature of mental time travel. In this entry, we will assess the evidence for such systems in animals. Asking whether animals possess such episodic capacities for both the past and the future would help understand the function of the episodic cognition in an evolutionary perspective.

## Episodic-Like Memory in Animals

There is an important debate as to whether mental time travel is unique to humans or shared with other animals. Bischof-Köhler (1985) claimed, for instance, that it is impossible for animals to anticipate future states because they are bounded into a present defined by their current motivational state, and Tulving (1983) suggested that animals do not remember personal past experiences. The "mental time travel" hypothesis stated also that the ability to mentally re-experience or pre-experience one's personal event is uniquely human (Suddendorf and Corballis 1997). Even though the debate is still vivid today, opinions have evolved since 1997 (e.g., Corballis 2013), in particular through research showing sequential replay in the rat hippocampus suggesting anticipation of future paths in a maze, as they either correspond to path rats have not actually taken or path rats previously took but in a temporally reversed order (Gupta et al. 2010). It led the author to admit that the difference between human and other animal's mental time travel ability might be one of degree and not of kind.

One issue is the definition of episodic memory in terms of consciousness, i.e., of autonoesis and chronesthesia mentioned above. Phenomenological aspects of episodic memory are usually investigated through verbal tasks in humans. A classical approach is to ask whether adult humans are able to verbally express what they recall in opposition to what they know during an interview, giving details of when and where they learnt the information. As these tests are highly dependent on verbal abilities, they are not relevant for infants and toddlers, as well as animals. As no conclusive experiments have been developed to study the phenomenological aspects of episodic recollection in the absence of agreed nonlinguistic criteria, it remains impossible to ask these individuals, be they nonverbal animals or preverbal children, whether they know or remember something.

The study of episodic cognition in animals needs to rely on behavioral measures that can be objectively tested. Clayton et al. (2003a) suggested three main behavioral criteria to investigate episodic memory in animals, namely, the content (i.e., “what” happened, “when,” and “where”), structure (i.e., the three features are bound together and integrated into one and the same episode), and flexibility (i.e., cardinal features of a declarative as opposed to a procedural system) of the memory. This minimalist view, circumventing the phenomenological aspects of episodic memory, refers to “episodic-like” memory.

The **content** behavioral criterion of episodic-like memory is based on Tulving’s original definition (i.e., “a system that receives and stores information about temporally dated episodes or events, and temporal-spatial relations among these events” Tulving 1972). This definition means that an episodic memory provides information about “what” happened as well as “when” and “where” it happened. According to the authors, the “when” component is crucial as episodic memory is temporally unique, whereas the spatial component (where) and the event itself (what) can be shared by several episodic memories. The **structure** behavioral criterion of episodic-like memory implies that the content

must represent an integrated representation of the three components acquired through a unique encoding. In other words, the “what,” “when,” and “where” must represent the same episodic memory. The **flexibility** behavioral criterion of episodic-like memory states that this integrated representation should be reused flexibly when required. Indeed, episodic memory is a subpart of the declarative memory system which supports the flexible deployment of encoded information.

The description of these three behavioral criteria has allowed researchers to start investigating, at least from a behavioral point of view, whether or not this cognitive ability would possibly be present in nonhuman species. A wide range of species has been studied during the past decades using this theoretical background; it is noteworthy that researchers were differently assessing the temporal component of episodic-like memory. In the following sections, we will review some of the studies using different definitions of this component.

### Studies Using the What-Where-When Criterion

Time can be defined as a continued and linear movement occurring irreversibly from the past through the present to the future. One single exception is the capacity of mental time travel allowing one to look back into the past and look forward into the future. Episodic memory is thus deeply rooted in temporality. Measuring this temporality can be done in several ways. Friedman (1993) discusses three main different theories to consider time. The first focuses on the event’s distance from the present. The remembered event is dated based on the time expired from the actual present (distance-based theory: i.e., how long time ago). The second approach assumes that the event itself shares information about the age of the memory (location-based theory or absolute timing theory: e.g., date of the calendar). The last approach is based on the relative time of occurrence of the memory where the date of the memory is determined according to other events (order-based theory: i.e., event B occurred after

event A and before event C). In this conception, the date of the memory is determined in relation with other events (before/after judgments).

Time is a process of active, repeated construction. In the following section, we will give some behavioral examples of experiments using these different approaches to investigate episodic-like cognition in animals.

**What-Where-When (In Terms of How Long Ago)**

Clayton and Dickinson (1998) were the first to experimentally test episodic-like cognition in animals, by using the three behavioral criteria (Fig. 1). In their original experiment, California scrub jays (*Aphelocoma coerulescens*) were able to learn that wax worms (preferred food item) would degrade after a long delay (124 h) but not after a short delay (4 h) and that nonperishable food (peanuts, non-preferred food item) would be available at both delays. Birds could cache the worms and the peanuts in a tray during the study phase and then retrieve their caches after 4 or 124 h at test. After the short interval, birds searched in the area where they cached the worms, and after the long interval, the jays searched in the area where they cached the peanuts. It seems then

that these birds were able to recall what they cached, where, and when. The following studies showed that this result was not due to familiarity cues and that the birds learned the rule by which food would be degraded and how long it would be eatable, forming an integrated representation of the what, the where, and the when. This representation was also flexibly accessed as the birds continued to respond appropriately even when the rule about the delays or the food changed (Clayton et al. 2003b). Recent study showed that magpies (*Pica pica*) were also able to retrieve what was cached, where, and when (Zinkivskay et al. 2009).

The episodic-like memory about what happened, where, and how long ago was also investigated in mammals such as rats (Babb and Crystal 2006). In their experiment, the rats were trained to discriminate what, where, and when they encountered food. Rats were placed in an 8-arm radial maze where distinctive food (grape, raspberry, i.e., preferred food items) or nondistinctive food (regular chow, i.e., non-preferred food items) pellet was available. During training, rats were allowed to visit four arms and returned after a short or long interval to the maze where all the arms were open. During the study phase, the arms containing chow pellet never replenished until the next trial,

**Episodic Memory, Fig. 1** Procedure of Clayton and Dickinson (1998) what-where-when task. 4 h and 124 h training and trials experimental conditions and contents

of the caching trays. During caching, birds could cache only on one side of the tray, as the other side was covered

while the arms containing grape and raspberry replenished after a long (6 h) retention interval but not after a short (1 h) interval. The arms that were closed during the study phase were filled with chow pellet at test. Results showed that rats were more likely to revisit grape and raspberry locations after long than short delay. Moreover, rats were able to adjust flexibly their behavior when one flavor was devalued. This study showed that rodents are able to encode the content of episodic-like component. Another study showed episodic-like abilities in meadow vole (*Microtus pennsylvanicus*; Ferkin et al. 2008). Male meadow voles can detect when a female is in best disposition for reproduction, a period called postpartum estrus (PPE). In this study, male meadow voles encountered two females in two different locations. One female was pregnant and about to enter the PPE period, while the other was neither pregnant nor lactating. After 24 h, the male was replaced in the same empty maze. At this time, the pregnant female was now a PPE female. The male spent significantly more time in the location of the PPE female. Results also showed that when males encountered a PPE female and a female who was neither pregnant nor lactating during the study phase, at test, males would spend equivalent time in both locations 24 h later as the PPE female was now a lactating female. Thus, meadow vole males were able to remember which female (what) was in the best period for reproduction after a single encounter (when) and in which location he could find her (where). What-where-when abilities were also found in primates (Martin-Ordas et al. 2010).

More surprisingly, episodic-like abilities were also found in invertebrates. Cuttlefish are part of the cephalopod mollusk's family. They possess a rich behavioral repertoire making them a good model for investigating complex cognitive abilities. Following the original study of Clayton and Dickinson (1998), Jozet-Alves et al. (2013) presented cuttlefish with similar what-where-when paradigm. On every trials, two distinct emplacements in the tank of the animals were spotted with identical visual cues. When the cuttlefish went close to one of these visual cues, a crab and a shrimp were simultaneously placed in front of the cues. Cuttlefish were then allowed to catch

one of the preys. After a short delay (1 h), the non-preferred prey was still available at the previous location, while the location associated with the preferred prey was not rewarded (Fig. 2). After a long (3 h) retention interval, both locations were reinforced. Results showed that cuttlefish went significantly more close to the visual cue associated with the non-preferred prey after a short interval, while they went significantly more to the visual cue associated with the preferred prey after the long interval. Cuttlefish flexibly adapt their foraging behavior according to the delay of replenishment of different preys, which represent the first episodic-like evidence in an invertebrate.

### What-Where-Temporal Order (Relative Timing)

Another way to investigate episodic-like memory is to consider the “when” component as a relative occurrence of the event. In their study, Fortin et al. (2002) showed that rats could remember series of odors previously encountered presented without any specific spatial cues, while rats impaired with hippocampal lesions showed severe and selective difficulty to recall the sequential order of the series of odors. However, rats with hippocampal lesions were able to recall odors that recently occurred. Hippocampus is known to be involved in episodic cognition. Authors argue that hippocampal network is associated with sequential events composing an episodic memory as rats could remember which odors (what) occurred in which order (when) and in which location (where). In another study, rats were trained to remember a sequence of four odors displayed in four different locations on a platform (Ergorul and Eichenbaum 2004). According to the authors, rats were able to recall which combination of odors (“what”) was presented in which location (“where”) and in which specific order (“when”).

### What-Where-Which

In the original what-where-when paradigm, context was mostly defined as the place and time in which the event took place. Some researchers argue that the “when” component serves to distinguish the remembered event with similar experiences and therefore to context, as opposed to the temporal representation which is important

**Episodic Memory,**

**Fig. 2** Procedure of the Jozet-Alves et al. (2013) what-where-when task. Each trial consists of two phases: during Phase 1, the cuttlefish learn which prey is associated with which visual cue; during Phase 2, the cuttlefish are tested either after a short (1 h) or a long (3 h) delay. After the short delay, the nonpreferred prey is available but not the preferred prey. After the long delay, both prey is available

E

(Eacott and Norman 2004). Thus, the “when” component can be changed into a unique “which” component retrieving contextual information and being comprised in an integrated representation of what-where-in which context episodic-like memory. Moreover, the original what-where-when paradigm relied on natural food-storing habits of scrub jays, and the adaptation of the paradigm with different species can be somewhat tricky. Eacott and Norman (2004) have based their paradigm on the natural tendency of rodents to explore novelty leading to a preference for exploring a novel object over a familiar one. Object recognition tasks are made of two main phases. In the first phase, animals are presented with several objects. In the second phase, a familiar and a novel object are presented at the same time. As rats are neophilic, they will explore significantly more time the novel object instead of the familiar one. In their study, during the test session, rats were presented with two familiar objects in a specific context and location. One of the objects was placed in the same context and

location than previously, but the other object was placed in another context and location. Results showed that rats explored more time the object placed in another context and location, showing that rats formed integrated representation of the object, the context, and the location at the encoding. In a more recent study, Eacott and Easton (2007) replicated the what-where-which experiment with another protocol. In their study, rats were placed in an E-shaped maze presented in a specific context (e.g., black). During 3 min, rats could explore the maze where two novel objects (A and B) were placed in the left and right arms. Then, rats were placed in a similar E-shaped maze in a different context (e.g., mesh). Similarly, they could explore the maze for 3 min where the same objects were placed in reverse locations. After this exploration phase, rats were placed for 8 min in habituation chamber with one of the object (e.g., A). At test, rats were placed in one of the previous contexts with objects in their context-specific location. Results showed that rats explore significantly more the unhabituated object showing

**Episodic Memory, Fig. 3** Procedure of the Eacott and Easton (2007) what-where-which task. Rats were placed in the start arm (S) in the E-shaped maze in one context. After 3 min of exploration of two novel objects (A and B), they were placed in a second E-shaped maze in a novel context,

with the same objects in reversed position for further 3 min. Rats were then transferred into a habituation chamber with the object (e.g., A) before returning to one of the previous context

that rats were able to recall what-where-which episodic-like memory (Fig. 3). This modified version of the episodic-like memory was also used in domestic animals showing that this cognitive ability is not negatively impacted by domestication. In an adapted version of the what-where-which task, domestic pigs (*Sus scrofa*) showed similar abilities to recognize the less familiar object/location/context configuration (Kouwenberg et al. 2009). Episodic-like memory for the context was also showed in zebrafish (*Danio rerio*; Hamilton et al. 2016). Fish were able to remember which object they previously encountered, in which location, and in which context they saw it.

### Other Ways to Investigate Episodic Cognition

The what-where-when paradigm is now a widely renowned paradigm to investigate episodic-like memory. However, other ways are also used

to address episodic-like memory. First, some researchers question the validity of this paradigm suggesting that it would rely on semantic rather than episodic processes. Indeed, the investigation of episodic-like cognition in animals often depends on rule learning procedures, and researchers argue that animals expect of being asked. It would then be necessary to investigate episodic-like cognition with “unexpected questions” to ensure that animals do not perform a task with semantic information processing. Another way to assess episodic-like memory is to study source memory which is the ability to retrieve the origin of a memory. Source memory specifically allows to distinguish between two episodic memories by remembering specific features of the episodic memory which were present when the memory was formed.

### Unexpected Question

To ensure that the what-where-when criterion for episodic-like memory is dissociated with semantic memory processes, Zentall and collaborators (2008) suggested to investigate episodic cognition

in animals using an “unexpected question.” They argue that most research with animals is based on rule learning procedures, such that animals are presented with classical conditional discrimination associated with retention intervals. For the authors, the what-where-when task for animals would actually rely on semantic memory or rule learning instead of episodic memory because animals expect to be asked to retrieve a specific information. In their experiment, pigeons were trained in a conditional discrimination task. Animals had to discriminate between colors (red vs. green) and positions (vertical vs. horizontal) according to an initial stimulus displayed at the beginning of the trial. Colors were associated with the position of this initial stimulus (e.g., if the initial stimulus was displayed on the left side, pigeons had to peck a red key and inhibit pecking a green key), and position discrimination was associated with the color of the initial stimulus (e.g., if the initial stimulus was yellow, pigeons had to peck the vertical key). At the end of vertical versus horizontal discrimination, if the correct comparison has been selected, pigeons were rewarded by pecking an orange key. At test, pigeons were presented with similar position

discrimination task, except that pecking the orange key was followed by red and green key choice. The red and green keys were reinforced equally. Results showed that pigeons remembered the rule associated with the red/green discrimination (i.e., choose the color according to the left/right location of the preceding stimulus) even though the question was completely unexpected. Other researchers used unexpected questions to investigate episodic memory, for instance, Skov-Rakette and collaborators (2006). They used a what-where-when paradigm asking pigeons in three separate matching-to-sample tasks (old-new recognition task: in matching-to-sample tasks, animals are rewarded if they respond to a stimulus that was encountered recently) (Fig. 4). In the “what” task, pigeons had to select the recently presented item. In the “where” task, animals had to select the location where the stimulus was recently presented, and in the “when” task, pigeons had to report how long ago the stimulus was encountered (3 s vs. 6 s). Once these tasks were learnt, the pigeons were presented with an unexpected configuration of the experiment in which pigeons had to perform the different tasks in random order. Animals could

**Episodic Memory, Fig. 4** Procedure of the “unexpected task” designed by Zentall et al. (2008). During the first phase, animals were trained to peck a side key (W) and then to peck a center triangle. If the initial side key was on the left, pigeons had to peck the red key (R+) to get a reward. If the initial key was on the right, pigeons had to peck the green key (G+). The position of the red and green comparison stimuli was counterbalanced. During the

second phase, yellow and blue keys were associated with vertical- and horizontal-line comparison stimuli, respectively. Pigeons had to peck the orange key (O) on the center, which was reinforced if the correct comparison had been selected before. Test trials replicated the second phase procedure except that a peck to the orange center key was followed by choice red and green side keys

not expect which tasks or which stimuli were going to happen next.

This “unexpected question” paradigm was also used in mammals such as rats which incidentally learned the presence or the absence of food in a radial maze and were unexpectedly asked about it (Zhou et al. 2012).

### Source Memory

Another way to investigate episodic memory is to consider the source of the memory, in other words a conscious awareness about how one knows about the informational content of the memory, for example, did I read it or did I hear it? Another way of expressing this idea is to argue that the “memory of the source” allows one to retrieve the origin of the memory by recollecting the information encoded when the memory was formed, constituting the context of the prior situation, and making the memory episodic. Source memory is essential in everyday life as it contributes to control the reliability of our beliefs, ideas, and memories (Johnson et al. 1993). Troubles in recalling the source of information can be very disturbing and, in the worst cases, lead to delusion and confabulation (the memory of the source contributes to the subjective experience of autobiographical recollection (i.e., the feeling that a memory belongs to one’s own past; Johnson et al. 1993)). Indeed, the information contained in the memory (e.g., perceptive, contextual, sensitive, cognitive, semantic, affective) allows to relive the event encoded and to recognize the memory as belonging to one’s own past. It is important to mention that source memory is not fundamentally different from episodic memory, but rather it is part of the mental time travel process. (Both are linked such as one leads to the other) When retrieving the source of a memory, the information is not simply accessed, but combined with cue information in an integrated representation, forming the episodic memory (Tulving 1983). The source-monitoring framework of Johnson et al. (1993) describes the processes involved in making attributions about the origins of a memory, knowledge, or beliefs. They postulate that during remembering, records are evaluated and attributed to a particular source through decision processes. These decision

processes would allow retrieving of specific features labeling the memory, specifying a memory’s source. The ease and the accuracy with which the source of a memory is identified would be determined by the type and the amount of the memory characteristics reactivated in memory records (e.g., spatial, temporal, social context, perceptual, sensitive stimulations, or again cognitive operations), how unique these characteristics are for given sources, and the efficacy of the judgment processes by which sources decisions are made. Some characteristics are less significant than others to recall the source of a memory, depending on the prior situation. For instance, one can remember having been to the beach because he remembers the heat of the sun, the noise of the sea, the persons he was with, or the activities he did. In other words, the perceptive, sensitive stimulations and the social context are really significant to recall the source of this information. In another hand, the cognitive operations he performed during the prior situation will be less likely remembered and evaluated to determine the source of this memory.

Jonathon Crystal’s work with rats constitutes one of the first reports about source memory in animals (Crystal et al. 2013). In this study, rats had to remember whether they had encountered a preferred food (chocolate) with self-generated cues (i.e., finding the chocolate by themselves) or experimenter-generated cues (i.e., placement of the rat at the chocolate site) cues. When rats found the chocolate by themselves, they had the possibility to retrieve it at the same location, whereas when they were placed by the experimenter in the chocolate location, the latter was not refilled afterward. Rats selectively adjusted revisits to the chocolate location based on source information. When the experimenters temporarily inactivated the CA3 region of the hippocampus with lidocaine, performances during this task were impaired. This result suggests that source memory is dependent upon an intact hippocampus.

Source memory has also been investigated in great apes with delayed matching to sample procedure where monkeys showed cross-modal recognition abilities of conspecifics (i.e., they

confused the identity of a monkey they saw with a monkey they heard; Adachi and Hampton 2011) or using item and source memory dissociation (i.e., monkeys learned to select the image from one source and to avoid the other; Basile and Hampton 2017). However, the study of source memory in animal is really underrepresented in the scientific community, and there is an urgent need to design behavioral tests to investigate it.

## Episodic Future Thinking

In this entry, we have focused on the retrospective component of episodic cognition. Episodic future thinking (or episodic foresight) is the ability to pre-experience (i.e., imagine) or anticipate future personal events. At first, it seems that episodic memory and episodic future thinking represent two opposite sides of mental time travel. However, there is growing consensus that episodic memory is intrinsically linked with episodic future thinking. Scientists argue that the real function of episodic memory would be to increase survival and fitness in present situations and future potential scenario. Thus, episodic memory would not be a memory of the past only but would actually be turned toward the future. Memories are made for the future: that's why they are so labile and flexible and forward-looking.

Investigating episodic foresight requires behavioral criterion as well. Behavior will have to be independent of current motivational state to be considered as demonstrating episodic foresight. This criterion is crucial because two identical behaviors can have totally different meaning in terms of episodic foresight. As an example, this morning I went to buy some food because I was hungry; it does not represent an anticipation on future needs as my behavior answers a current motivational state (i.e., hunger). However, if I went to buy food while being satiated because I know that I will be hungry in the evening, it can be considered as an episodic anticipation of future needs.

The Bischof-Köhler hypothesis postulates that animals always act following current motivational goals, leaving the ability of episodic foresight

unique to humans. However, studies demonstrate that animals show future-thinking abilities in a wide variety of domains. As an example, recent studies have shown that rats mentally pre-experience navigation and route planning, where hippocampal activations were similar when the rodents travelled through the routes and when they were about to pursue them (Pfeiffer and Foster 2013). Emery and Clayton (2001) showed that jays were able to adjust their caching strategies to reduce the risk of being stolen by a conspecific. Birds could cache food either in private or being observed by another bird. The interesting finding was that birds that have stolen another bird's caches previously then re-cached their food at recovery when they had the opportunity to do so in private, whereas naïve birds that had not experience of stealing from another bird did not re-cache their food. This result shows that re-caching behavior is triggered by previous personal experience of stealing. In other words, birds having stolen from another bird rely on their previous experience of stealing to adjust their caching strategies, which constitutes evidence for future-oriented behavior. After all the only point of re-caching the food is if one is able to recover it at some point in the future.

Other studies have shown that Californian scrub jays (*Aphelocoma californica*) would cache the food type that they wished to eat at the time of recovery as opposed to at the time of caching (i.e., their current need is not the same at the time of caching), thereby demonstrating that they could cache with the future in mind and dissociate current from future motivational states (Correia et al. 2007). Subsequent studies with Eurasian jays (*Garrulus glandarius*; Cheke and Clayton 2012) demonstrated that these birds could also cache for two future motivational states. Studies of tool use and forethought showed that chimpanzees (*Pan troglodytes*) and orangutans (*Pongo abelii*) were able to select a convenient tool to obtain a food reward in the future independently of their current motivational state (Osvath and Osvath 2008). Recently, similar findings were found in ravens (*Corvus corax*; Kabadayi and Osvath 2017) and in New Caledonian crows which were able to plan ahead on sequence of

tool behavior in metatool problems (Gruber et al. 2019). Taken together, these studies show that corvids can remember specific past events about what happened where and when and can also plan ahead, flexibly adjusting their strategies based on what they predict about what the future will hold, and that they can make these cognitive decisions independently of current desires.

## Conclusion

According to Tulving's definition, episodic memories consist of recollections of what, where, and when a past event occurred (Tulving 1972). Based on this conception, Clayton and Dickinson (1998) suggested three behavioral criteria for assessing episodic-like abilities in animals, devoid of the complications of the phenomenological characteristics that accompany human episodic memory and are evaluated through verbal report. Clayton and Dickinson (1998) were the first to demonstrate episodic-like behavior in a nonhuman species by developing this what-where-when behavioral paradigm. Subsequent studies have shown that episodic-like memory is found in a wide range of species including mammals, birds, fish, or invertebrates. Although all of these studies have used a what, where, and when paradigm of some sort, the "when" component has been investigated in multiple ways. Some studies have focused on how long ago the event was encountered following Clayton and Dickinson's original paradigm, while others have studied the relative occurrence of the stimulus (i.e., temporal order; Fortin et al. 2002; Ergorul and Eichenbaum 2004) or the context encoded with the event ("which"; Eacott and Norman 2004; Eacott and Easton 2007; Kouwenberg et al. 2009; Hamilton et al. 2016). Contextual information is specifically investigated in source memory studies, as source memory is the capacity to recall the origin of a memory, that is, recalling specific features pertaining to the encoded event (e.g., temporal and spatial location, perceptual, sensitive, cognitive information). Source memory raises the question of the link between episodic and

semantic memory as it involves decision-making processes and judgments about the episodic memory. Some researchers suggest that the what-where-when paradigm involves no more than semantic process, and it has been proven to be difficult to create a what-where-when experiment without rule learning explanation. A possible alternative would be to add an unexpected question as proposed by Zentall et al. (2008) whose aim is to provide animals with a novel configuration of the task, where animals have to use previously acquired incidentally encoded knowledge to formulate an answer (i.e., encoded without the expectancy of being asked).

Young children, just like animals, cannot verbally relate their previous past experiences, and researchers need to use a similar behavioral approach to investigate their episodic cognition. Some researchers, for example, Russell and Thompson (2003), have done just this by applying the food caching paradigm (Clayton and Dickinson 1998) and testing preverbal children aged between 14 and 25 months. Their results showed that children between 22 and 25 months could perform the task above chance, reproducing scrub jay performance. Other behavioral studies were used to investigate deferred imitation and source memory in preverbal children. Interestingly, these studies show that nonverbal animal tasks can be reliably used with preverbal children, which can help to follow the ontogenetic trajectory of episodic cognition. Taken together, these studies provide evidence that animals do have episodic-like memory. At issue is whether and to what extent episodic-like memory is like episodic memory, in other words whether the ability to remember unique past experiences about what happened where and when involves mental time travel with all its associated phenomenological construes. It is a question that remains controversial, but it is fair to say that the behavioral components of episodic memory, in particular the what-where-when methodology, have led to the development of a comparative cognition approach, from corvids to cephalopods and chimpanzees and from the nonlinguistic to the preverbal.

## Epistasis

Debojyoti Pal

Radiation Biology and Health Sciences Division, Bio-Science Group, Bhabha Atomic Research Centre, Trombay, Mumbai, Maharashtra, India

## Synonyms

Epistatic interaction; Gene interaction

## Definition

Epistasis is a genetic phenomenon in which the function of one genetic locus is affected by the product of another genetic locus.

## What is Epistasis?

### Introduction

The term epistasis has originated from the Greek root words “epi” meaning “upon” and “stasis” meaning “stopping.” This terminology highlights the essence of the genetic phenomenon epistasis; the ability of one gene to bring about stoppage or affect the functionality of another gene’s function. Or to put it in a different perspective, it is the dependency of one gene’s functionality on the modifying effect of other regulatory “epistatic” genes (Alberts et al. 2014).

Usually, epistasis takes place due to the interconnected nature of the pathways on which the gene products operate (Sanders and Bowman 2014). Often, the final phenotype is produced by combinatorial effect of gene products from multiple loci. An alteration in a pathway at one place can have far-reaching effects, such as rendering downstream effectors nonfunctional (Watson 2014).

## How to Detect Epistasis?

The traditional and simplest way to detect the presence of epistatic interactions between two genes is by examining the phenotypic ratios of the F2

generation offspring of a dihybrid cross (Phillips 2008). In the first generation, homozygous parents differing in allele composition at two loci are mated. The F1 generation is heterozygous at both the loci, inheriting alleles from both parents. Mating between heterozygous individuals of F1 generation is the actual dihybrid cross and it produces F2 generation offspring. In absence of epistatic interactions, the phenotypic ratio of F2 generation is expected to be 9:3:3:1, as can be easily demonstrated by the punnet square (Russell 2005).

How to Interpret the Punnet Square?

The punnet square is used to diagrammatically represent the possible outcome of a cross, such as a dihybrid cross (Snustad and Simmons 2003). As it is evident from Table 1, the dominant alleles are expressed without any epistatic interference and give rise to the 9:3:3:1 ratio of phenotype among the offspring. Nine genotypes have at least one copy of each dominant allele and express the dominant phenotype of both loci. Three genotypes have at least one dominant allele of gene A and two recessive alleles of gene B. Hence they show dominant phenotype of gene A and recessive phenotype of gene B. Three genotypes have at least one dominant allele of gene B and two recessive alleles of gene A. Hence they show dominant phenotype of gene B and recessive phenotype of gene A. One genotype has two recessive alleles for both loci and thus shows recessive phenotype for both genes.

Distinguishing Linkage and Epistasis

A shift from the expected 9:3:3:1 ratio indicates epistasis or linkage (Russel 2009). Linkage can skew the expected phenotypic ratio. The extent of

shift in linkage is dependent on the intergenic distance between the loci under consideration and is a continuous phenomenon. On the other hand, epistatic interactions give rise to definite fixed ratios of offspring phenotypes, depending on the type of epistasis. Epistasis also causes clubbing of two or more phenotype classes into one. Thus a reduction in phenotype classes is an indicator of epistatic interactions. By studying the observed ratio, one can draw inferences about the type of epistasis in play. Some of the most important epistatic interactions are described as follows:

Dominant Epistasis

In dominant epistasis, the dominant allele at one locus masks the phenotype of both alleles at the second loci.

For example in foxgloves, allele B produces dark-red pigment and allele b produces light-red pigment in flowers. At loci A, recessive allele a causes pigment distribution in flowers while dominant allele A restricts pigment distribution. As a result, the presence of dominant allele A renders flowers colorless irrespective of the allele composition at loci B.

It is characterized by a 12:3:1 phenotypic ratio. Twelve genotypes have at least one copy of allele A and therefore would produce colorless flowers. This is dominant epistasis at work. Rest four genotypes have two copies of allele a and thus they are colored. Three of them have at least one copy of dominant B allele and are dark red while one is light red due to presence of two copies of recessive allele b.

Recessive Epistasis

In recessive epistasis, the presence of two recessive alleles at first locus masks the phenotype of both alleles at the second loci.

For example, gene A is responsible for eumelanin synthesis and gene B controls eumelanin distribution in certain dog breeds. In the presence of allele B, eumelanin distribution is complete while allele b reduces eumelanin distribution. As long as at least one copy of allele A is present coat color is either black due to presence of allele B or chocolate due to reduced distribution by two copies of allele b. In recessive homozygous offspring having two

Epistasis, Table 1 Punnet square showing offspring genotype of a dihybrid cross

|              |    | Female gametes |      |      |      |
|--------------|----|----------------|------|------|------|
|              |    | AB             | Ab   | aB   | ab   |
| Male gametes | AB | AABB           | AABb | AaBB | AaBb |
|              | Ab | AABb           | AAbb | AaBb | Aabb |
|              | aB | AaBB           | AaBb | aaBB | aaBb |
|              | ab | AaBb           | Aabb | aaBb | aabb |

copies of allele a, no eumelanin is synthesized and hence coat color is yellow, irrespective of allele composition at loci B, which control distribution of allele A generated eumelanin.

It is characterized by 9:4:3 phenotypic ratios. Four genotypes contain two copies of recessive alleles of a and thus have yellow colored coat. These are the individuals in which the recessive epistasis is operative. Recessive allele a in homozygous state masks the phenotype at locus B.

Nine genotypes possess at least one copy of allele A and at least one copy of allele B and hence are black. Three genotypes have at least one copy of allele A and two copies of allele b. Therefore they have reduced pigment distribution and have chocolate coat color.

### Duplicate Recessive Epistasis

This is also known as complementary gene interaction. Dominant functional alleles at both loci are required for the resultant phenotype. Presence of homozygous recessive alleles at either locus masks the phenotype.

For example, allele A and allele B produce enzymes which act on a biosynthetic pathway to produce purple flower color. Precursor X is converted to precursor Y by allele A. Allele B converts precursor Y to product Z, which gives purple color to the flower. In the absence of either dominant allele, product Z would not be formed and the flowers would be colorless.

This interaction is characterized by a 9:7 phenotypic ratio. Seven genotypes lack either dominant allele A or B or both and are thus colorless due to lack of complementarity between allele A and allele B products. The rest nine genotypes have at least one copy of dominant allele at each locus. As a result they can form the purple color-generating product Z and the flowers are colorful.

### Duplicate Dominant Epistasis

This is also known as duplicate gene interaction. In this case, dominant alleles at both loci have the same function. Hence, the presence of functional dominant allele at either locus is sufficient to give rise to the resultant phenotype. This is an example of redundancy in the biological systems.

Petal colors in snapdragons are governed by duplicate gene interaction. Both dominant allele

A and B can convert the precursor into functional pigment that gives color to the petals. It is characterized by a 15:1 phenotypic ratio. Only the double recessives are colorless. Rest of the 15 genotypes possess at least one copy of dominant allele on at least one locus and are thus capable of producing colored petals.

### Dominant Gene Interaction

In this interaction, dominant allele at either locus produces an identical phenotype but gives rise to a different phenotype when both dominant allele products are present.

For example, in squash fruit, double recessives give rise to long fruit shape. Dominant allele at only one locus gives rise to spherical fruit, irrespective of whether it is allele A or allele B. Both allele products seem to synthesize proteins which can produce spherical shaped fruit. Interestingly, in presence of dominant alleles at both loci, disk-shaped fruit is produced. Both allele products interact to produce this new phenotype.

It is characterized by a 9:6:1 phenotypic ratio. Nine genotypes have at least one dominant allele at both loci and thus interact to form disc shaped fruit. Six genotypes have dominant allele at only one locus and thus give rise to spherical fruits. One genotype is double recessive and produces long fruit.

### Dominant Suppression

In case of dominant suppression, the dominant allele at one locus suppresses the dominant allele phenotype at the second locus.

For example, feather color in chicken requires the dominant allele A that converts colorless precursor to colored pigment. Recessive allele a is unable to cause this conversion and hence recessive homozygous condition for allele a causes chicken to be colorless. Dominant allele B at the second locus causes inhibition of allele A function. As a result, the presence of copy of allele B suppresses allele A phenotype and chicken have colorless feather.

This is characterized by a 13:3 phenotypic ratio. Thirteen genotypes show colorless feathers. Nine out of 13 genotypes have at least one copy of dominant A allele but the simultaneous presence of at least one copy of dominant B allele masks the allele A phenotype. These nine are the offspring in which the actual dominant suppression is taking

place. Rest of the four genotypes are recessive homozygous for allele a and hence are anyways going to produce colorless phenotype, irrespective of presence (three genotypes) or absence (one genotype) of allele B. Three genotypes show the colored feather phenotype. These have at least one copy of functional allele A and no copies of functional inhibitor allele B, i.e., recessive homozygous for allele b.

### Epistasis in Humans

Just like in other organisms, epistasis is seen in humans too. The Bombay phenotype is an example of epistatic interaction.

ABO blood group is coded by gene I of which allele  $I^a$  and  $I^b$  are codominant. Allele products of  $I^a$  and  $I^b$  are glycosyltransferases and they act on the precursor oligosaccharide (H-antigen) to add N-acetyl galactosamine or galactose respectively to form antigen A or antigen B. The nonfunctional allele  $I^o$  produces no functional enzyme and hence does not modify the precursor oligosaccharide.

For the effect of  $I^a$  and  $I^b$  to be observed, the formation of the precursor is essential. Gene H controls the formation of precursor H-antigen by adding a fucose to its precursor. Dominant allele H is required for addition of fucose to the precursor of H-antigen. In recessive homozygous individuals containing two h alleles, no H-antigen is formed. As a result,  $I^a$  and  $I^b$  allele products cannot act in absence of H-antigen and the phenotype is similar to that of nonfunctional  $I^o$  allele. Thus the gene locus H has an epistatic influence on the gene locus I (Snustad and Simmons 2003).

### Conclusion

It may be concluded that epistatic interactions are highly prevalent in all forms of life. Understanding the epistatic relation between genes is essential for unravelling the complex network of interactions that take place at the molecular level to bring about the phenotypes visible to us.

Twin study method

## Definition

The equal-environment assumption (EEA) is a biometric model that predicts how far the monozygotic (MZ) and dizygotic (DZ) twins are correlated to each other upon their exposure to environmental effects which are of etiologically significance to the trait/traits under consideration (Kendler et al. 1993).

If EEA is not accurate in assessing the extent of correlation between MZ and DZ, then the considered additional similarities or traits based on genetic factors might be alternatively explained by environmental impacts.

The basic principal postulation of the twin method has been attributed by the fact that both MZ and DZ twin pairs are reared together experience similar environmental effects (Siemens 1924).

## Background Description

In 1968, Scarr introduced a test of EEA which assesses the influence of phenotypic similarity in twins of assumed versus true zygosity. After his discovery in course of time, numerous research innovations have been proposed to measure the heritabilities of wide variety of traits like height (Visscher et al. 2006) to autism (Liu et al. 2010) and even food preferences (Breen et al. 2006). However, many assessments for twins are based on twin pair analysis. Therefore, it is dependent on strong assumptions about the relative environmental likeness and its impact on modulating the development of identical (MZ) and fraternal (DZ) twins.

Since 1920, scientists in psychology and psychiatry also have employed the “classical twin method” to assess genetic elements governing psychological traits such as IQ and personality (Joseph 2004). This is because of the fact that fostered-together MZ pairs share 100% of their segregating genes, whereas under similar circumstances DZ share only 50%. Twin researchers have argued over the fact that MZ pairs resemble each other more for behavioral characteristics and disorders than do same-sex DZ twin pairs. This is mainly caused by the former’s greater genetic

similarities over the other. At the same time, most reviewers of the twin method have claimed that MZ pairs experience much more alike environments than DZ pairs, and consequently this greater environmental parity surprises genetic interpretations of twin method data (Joseph 2004). Looking back in time during 1960s most critics and many twin researchers agreed that MZ twin pairs experience more or less similar environments. They are treated more alike and are socialized to be more identical than DZ counterparts (Joseph 2004).

Societal connections impose a potential influence on shared physical features of MZ twins. MZ twins on an average are much closer to each other than DZ twins by a number of measures. Both this suggested closer bond between MZ twins and similar reactions from the family or society to the identically featured MZ twins could well encourage the behavioral enrichment of the children in the direction of greater similarity. In such conditions the incorrect acceptance of the EEA could lead to heritability estimations in twin studies that would be highly exaggerated, despite the fact that the characters under consideration were strongly environmentally influenced.

## Methodologies for Analyzing EEA

There are four major methodologies to test the weight of the EEA in twin studies (Kendler 1983).

1. In the first method the EEA predicts that resemblance in twins is governed by the similarity of impact by social environment which in turn reflects their degree of physical attributes.
2. The second method encompasses direct observation of twins in a social or family background where the behavior of other entities is divided into those which are self-initiated and which take place in response to twin behavior. In a study, it was found that very young twins and their parents hold excess resemblance in the parental treatment of MZ vs. DZ twins. The assessment was entirely directed to parental behavior which was in response to twin behavior.

3. The third method based on observations that definite and quantifiable parameters of the childhood and adult environments of MZ twins are more or less alike than that for DZ twins. As for example it has been surveyed that MZ twins generally share same dress or use similar kind of dresses, etc. which is not observable in case of DZ twins (Loehlin and Nichols 1976; Kendler et al. 1986, 1992c).

Moreover, as it has been found that adult MZ twins are much frequent in contact with each other than that of the same sex DZ ones (Kendler et al. 1986, 1992c; Rose et al. 1990). Now the problem arises, on account of the fact that if all the environmental experiences affect twin similarity then this might violate EEA interpretation. So in this case, the detection may be done by using correlative study by separating each of the zygosity group and assuming the degree of environmental influence on both childhood and adulthood (Loehlin and Nichols 1976). In this regard, Kendler and his group found that there were no observable association between childhood and adulthood environmental similarity for assessing certain psychological disorders. Therefore, this kind of study has certain limitations like the frequency of connection between adults to that of phenotypic similarity between twin pairs are very much unpremeditated and casual as addressed by Lykken et al. (1990). He also pointed out the fact that the degree of phenotypic resemblance may directly or indirectly impart relation with frequency of contact should considered as an influential factor.

4. The fourth method suggests a comparison of trait similarity as a function of both “real zygosity” as assessed by investigators and “perceived zygosity” as observed by twins and their parents (Scarr 1968). This study method has a definite advantage over the previous ones. In the previous studies, only one potential source is taken for assessment like dress used by twins but in this case investigators incorporate global test for all potential environmental factors that influence the zygosity associated attitudes and expectations.

## Application

- Twin study methodology is generally applied on the examination of physical similarity in different psychiatric disorders like major depression, generalized anxiety disorder, phobia, alcoholism, and bulimia.
- The applicability of EEA for MZ and DZ twin study may extend to both prenatal and postnatal environment.
- In utero, twins are distinguished in terms of whether they share a chorion, and thus have a single placenta. MZ twins can be of two types, like monochorionic (MC) or dichorionic (DC) depending on the timing of their division. On the other hand, DZ twins are always DC. MC twins always share the same placenta and if this makes them more similar than DC and DZ twins then a specific example of violation of the trait-relevant EEA (Prescott et al. 1999).
- Twins do not differ in terms of their disease-related features (Andrew et al. 2001). An entire issue of the journal *Twin Research* was based on the fetal origin of disease hypothesis (Lambalk and Roseboom 2001) whereas none of the articles dealt with behavioral phenotypes.

## Drawbacks

- Critics have debated over years that twin study method cannot unravel the potential roles of genetic and environmental influences on each other.
- On the other hand, geneticist from other disciplines like political science couldn't furnish convincing opinions than their predecessors in psychology and psychiatry in figuring out the inter-effect of environment and genes on each other (Joseph 2010).
- The study principle also could not nullify the tenet that EEA should be tested “trait-by-trait,” or rather specifies the evaluation, very similarly in a way that most of the behavioral geneticists currently assess the family studies.

## Concluding Remarks

The traditional twin method study between MZ and DZ is generally assumed by EEA. The associative environmental impacts correlative to MZ and DZ are also considered for the study. Numerous diseases and genetic disorders exemplifying the MZ/DZ conditions are basically assessed by EEA. Many of the MZ-DZ pedigree studies interpret several doubtful scientific outcomes thereby giving the entry to nonviable accesses of EEA study. Thus, sometime makes gateway to mislead operational definition, which would rather have been called “heritability.”

## Introduction

The equids (Equidae) comprise zebras, donkeys, and horses. They are not considered to be independent taxa and can be crossbred, with wild animals sometimes crossbreeding in overlapping habitats. In general, the resulting equid hybrids are called zebroids (zebra and any other equid), mules (male donkey and female horse), or hinnies (male horse and female donkey). Other informal

labels include zebrules, dedonks, and zorses. The hybrids are usually infertile.

Equids differ in their social organization and have different habitats (Klingel 1972; Fig. 1). Some species are exclusively wild, and some include domestic types. In evaluating their cognitive capacities, it is important to consider the species' social and environmental challenges (Griffin et al. 2017). Only by knowing the conditions to which animals have to adapt can their cognitive capacities be compared in relation to other species. For example, if feral and wild equids do not encounter humans on regular basis, they may not need to learn how to read human-given cues, even though they may be able to do so when living close to humans. They may, however, need to learn to read cues given by other species with which they cohabit. Therefore, the equids' social systems and environments will briefly be described. The state of the art in cognition research will follow.

Cognition research is scarce in the wild species, the Przewalski's horse, zebras, and wild asses. This is mostly due to the fact that these species are difficult to observe because they avoid contact with humans, they live in remote areas, and because only a few animals are left in nearly extinct zebra and wild ass species. During the last two decades, cognition research in domestic horses has advanced in giant steps. For horses, only milestones in cognition research and some interesting approaches which are worth following up with are presented.

## The Zebras

### Social Organization

Zebras comprise three exclusively wild species, plains zebra (*Equus burchelli*), Cape mountain zebra (*E. zebra zebra*), and Grevy's zebras (*E. grevyi*). Zebra species can be assigned to type I and type II social systems (Klingel 1972; Fig. 1). Plains zebra (*E. burchelli*) and Cape mountain zebra (*E. zebra zebra*) live in the African Savanna and form type I social systems. They live in harem groups with several females, their offspring, and usually one or a few mature males.

**Equine Cognition, Fig. 1** Equid social systems. In type I social organizations, depicted above, females (♀), offspring (juv), and males (♂) live in mostly stable groups with usually one alpha male and several females and their offspring. Whereas in type II organizations depicted below,

males protect particular habitats and dominate loosely bonded females and males that travel through these areas (Klingel 1972). In recent publications *Equus quagga* is termed *Equus burchelli*, *Equus zebra* is *Equus zebra zebra*, and *Equus africanus* is referred to as *Equus asinus*

Surplus males gather in bachelor groups. Several of these subgroups may form herds of about 200 up to 1,000 animals (Klingel 1972). Mostly linear hierarchies are formed within and between subgroups, and animals are bonded with fellow group members, so they form so-called social bonds. The linearity of the hierarchies and the numbers of social bonds between group members varies from group to group (Fischhoff et al. 2007).

Grevy's zebras (*E. grevyi*) live in remote African mountains with little vegetation or water. They form type II social systems (Fig. 1). Solitary males defend a territory around a water source and mark the borders with feces (scent marks). The males claim mating rights over the females within their territory. Whether females form social groups depends on the resource availability. When food and water is scarce, females live alone with their offspring, but in periods with plenty of food and water, they form small groups.

### Social Cognition

Plains zebras protect their social bonds by intervening in the interactions of others (i.e., third-party intervention). Foals, yearlings, and adult mares intervene when certain group members exchange friendly (affiliative) behaviors. For example, they chase away an animal which grooms with their preferred group member.

Furthermore, yearlings and foals intervene when their mothers are attacked by stallions. They show submissive-type behavior, the so-called “snapping” or tooth clapping, which usually stops the aggression of the stallions immediately. Finally, stallions, in multi-male, bachelor groups, intervene in the courtship behavior of others, especially when females which are bonded to the intervening males are involved (Schilder 1990).

### Spatial Cognition and Movement Decisions

Abilities in spatial cognition allow plains zebras to find distinct paths for short- and long-distance movements (Brooks and Harris 2008). The exact mechanism is not certain. They use spatial memory to orientate on landmarks, but orientation on magnetic fields may also play a role.

Plains zebra group movements appear to arise out of a mix of cognitively undemanding self-organized movements and cognitively demanding decision-making. When movements are self-organized, group members synchronize their movements with other group members in their vicinity, mostly without making any decisions on whom to follow. However, zebras appear to decide whether to follow particular group members to some extent. For example, lactating females initiate movements toward water more often because of their enhanced need for water. Some zebras may

just follow more or less unconsciously, by movement synchronization. But, as the number of followers depends on the quality and the quantity of the initiating animal's social bonds within its group, it appears that zebras do make decisions about whether they follow all or just preferred group members (Fischhoff et al. 2007).

When Grevy's zebra females have to walk long distances to water sources, they have been described as leaving their sleeping offspring behind, while one or two mature animals stay with the "kinder garden" (Klingel 1972).

## The Donkeys

### Social Organization

Donkeys comprise the African wild ass (*Equus asinus*), Asian wild ass (*E. hemionus*), the Kiang (*E. kiang*), and domestic types (*E. asinus asinus*). Wild asses are close to extinction. All form type II social organizations (see above; Fig. 1). Some individuals in donkeys and wild asses appear to mark their territory with urine and feces (Klingel 1972). They avoid contact with humans and roam in steppe or semidesert habitats in very remote areas where they are not threatened by heavy hunting. In the past, herds comprised more than 1000 individuals, but this is now reduced to a few extant herds with less than 200 individuals.

### Social Cognition

So far, there has not been any research on cognition in wild asses, but some has been conducted in domestic donkeys. Anecdotal reports on strong bond formation between domestic donkeys have been scientifically confirmed. Donkeys recognize the individuals with which they are bonded and prefer to stay close to them (Murray et al. 2013).

### Spatial Cognition

Donkeys appear to have a good working memory for locations, for example, the point where food was removed from view through a barrier, and they demonstrated an understanding of object permanence, i.e., the understanding that objects which are not perceptible may still be present. They searched for a food bucket, which was

removed from view through a hole in the center of a simple V-shaped barrier by detouring around the barrier after ten and 30 seconds (Baragli and Regolin 2008). In a comparative approach, mules were superior to donkeys and horses in learning the position of a gap in a barrier. When the gap was moved from location A to location B, horses kept returning to the old, now closed gap (A), while mules and donkeys approached the old and the new gap (A and B) randomly (Osthaus et al. 2013). Mules and donkeys, therefore, showed a higher plasticity in reasoning about spatial conditions, i.e., in spatial cognition, than horses.

### Object Discrimination

When donkeys, mules, and horses were tested on how many pairs of particular patterns on paper cards they would learn to discriminate within 25 sessions. Five out of six mules, but only one out of six horses and none of the six donkeys achieved three different pattern pairs (Proops et al. 2009b). It has been suggested that the superiority of mules in discrimination learning is a matter of hybrid vigor. However, it remains a matter of debate whether the horses' gradual, and the donkeys' fast, decline in performance is due to attention loss rather than to discrimination learning capacities.

## The Horses

### Social Organization

The domestic horse (*Equus caballus*), the feralized domestic horse (*E. ferus caballus*), and the wild Przewalski's horse (*E. ferus przewalskii*) all form type I social organizations (Fig. 1), and they build social bonds with up to three partners. In contrast to the teaching of some traditional textbooks, harem and group stability varies considerably between groups. Some show stable core groups, but all-male "bachelor" bands are unstable in feral horse populations with only a few exceptions. Ninety to 100% of the male and 80–90% of the female offspring disperse from their natal groups when they reach maturity. Some females disperse and later return to their

original harems. Animals which frequently change groups are termed “switchers” (see for review: Linklater 2000).

### **Social Cognition**

Female horses form alliances for offspring protection. Their success in raising the offspring is higher when they are bonded to another female. Furthermore, horses protect social bonds through third-party intervention and seek for conflict resolution within their group. They intervene when horses are bonded to groom with others, and they chase aggressors away, especially when horses they are bonded to are challenged (Krueger et al. 2015). Horses even show post conflict resolution, by consolidating group members that were objects of aggression from others in the group. Uninvolved third parties (horses) stay close to and show friendly interaction toward recipients of previous agonistic interactions, i.e., winner–loser interactions, from which the challenged participant had to retreat (Cozzi et al. 2010).

The horses' social system can be described as a fission–fusion society. A fission–fusion society is characterized by frequent animal departures and returns within groups and within herds. Living in such a constantly changing system calls for the ability to identify departing and returning group members. In fact, horses identify their group members individually. They recognize group members by their whinnies, especially by calls which are used to stay in contact over long distances (Proops et al. 2009a). Furthermore, they recognize their group members by their outer appearance and the smell of their fecal marks (Krueger and Flauger 2011).

### **Humans: Part of the Horses' (Social) Environment**

The domestication of horses 3000–6000 years ago may have shaped interspecies communication abilities with humans (Fig. 2). Scientific evidence is yet to be established for the so-called domestication hypothesis in horses; this would require comparison between wild horses, domestic horses, and horses of different domestication durations and purposes, for their interspecies communication abilities. However, horses' skills

in responding to human facial and gestural cues have been known since the early twentieth century through the case of Clever Hans.

Clever Hans was claimed to have the arithmetic skills of a 12-year-old child. He presented the solutions to mathematical problems by tapping the number with his hoof. Although subsequent observations revealed that he could not count, he was, nevertheless, extremely skilled in reading subtle human facial expressions and body movements, which he used to decide when to begin tapping and when to stop. He even generalized the cues from his trainer to unfamiliar persons (Pfungst 1907).

The discovery of Clever Hans' “shortcut” to solving mathematical equations stigmatized cognition research in domestic animals, especially in horses, for about 100 years. Nobody dared to approach the evaluation of whether Clever Hans' skills in reading human given cues were unique or common in horses. Only in the last decade was research conducted in this area.

Today, we know that horses identify humans individually. Domestic horses are able to use human hand pointing gestures and human head and body orientation to find food. They orientate on the direction of human attention, for example, when humans turn away and stare in a particular direction. They distinguish between familiar and unfamiliar persons, generalize positive and negative experiences with humans from one person to another, and infer emotional states of humans from photographs. Some horses may have negative or positive expectations of human behavior acquired from previous encounters with humans. These expectations may even inhibit their performance in experiments. They may refuse to participate in a test if they believe humans will solve the task for them or if they are waiting for distinct signals to direct them to what they are expected to do (for human-horse interaction, see Hausberger et al. 2008; Schuetz et al. 2016).

### **Spatial Cognition and Movement Decisions**

Research in spatial cognition in horses is still puzzling. On one hand, short-term memory for the placement of objects and food has been said to be limited to 10–30 s. Furthermore, horses have been said to have a limited understanding of

object permanence, i.e., the understanding that objects which are not perceptible are still present, and limitations in some horses' spatial reasoning may hamper their performances in simple detour tasks (Baragli and Regolin 2008; Osthaus et al. 2013).

On the other hand, horses need cognitive capacities to stay with group members, to protect offspring, and to flee from predators together. Landscape cues have to be memorized for decisions on where to flee to and where to move the group to. A recent study on pattern discrimination showed that horses have a good spatial memory, and they prefer spatial cues over visible object-specific cues. They were better at memorizing the position of a food bucket and distal spatial cues in the experimental arena than at memorizing patterns on the food bucket (Hothersall et al. 2010).

Horses actively move other group members into a chosen direction. Group movements can be initiated by the despotic herding of alpha males, for example, in dangerous situations, when a larger or more dominant, competing group approaches the stallion shows herding posture and drives his whole group away. On the other hand, any group member may initiate movements by departure in Przewalski's horses and in feral horses (Kruger et al. 2014b). Movement initiations by departure are not exclusive to any particular individual, as has been claimed for so-called "lead" mares. Instead horses show a limited form of distributed

leadership, such that higher-ranking animals are followed more often, but no one individual has unique or permanent control over movement initiation (Kruger et al. 2014b).

Most horse movements appear to be self-organized, with individuals responding to the movement of other horses in their direct vicinity and with little need for cognitive decision-making. However, as in baboons, movement initiations of high-ranking, older horses may be perceived as being more reliable and therefore more advantageous to follow. The fact that social rank affects whether animals are followed or not implies that decision-making on the reliability of the potential initiator takes place (Kruger et al. 2014b). So far, recruitment of group members to join in the movement of an individual has not been observed in horse to horse interactions, despite expectations.

However, horses appear to recruit humans. Horses have shown distinct recruitment behavior toward humans when trying to direct humans to open a gate to allow access to food (Malavasi and Huber 2016; Fig. 2).

### Object Discrimination, Categorization, and Generalization

Object discrimination is the basis of recognizing landmarks for orientation and useful for recognizing food and predators. Some studies have shown horses to be able to discriminate precisely between

**Equine Cognition, Fig. 2** Human-animal referential communication in horses. Horses try to recruit humans to help them to get access to food, by (a) gazing to the experimenter or (b) pointing at a bucket with food behind a fence. The fence, a blue rope, is difficult to see. They

communicate their interest in the bucket to an experimenter facing in their direction, but showed less referential communication when the person turned around or walked away after releasing them into the experimental arena (Malavasi and Huber 2016)

**Equine Cognition, Fig. 3** Horses discriminate objects on computer screens. Horses were able to understand (a) the categories filled versus open center and (b) the concept small versus large (Hanggi and Ingersoll 2009)

objects. Horses learn object categories and concepts and even generalize them to unknown objects. For example, they learn the categories “filled versus open objects” and concepts of “always choose the smallest object” (Fig. 3). The horses applied the learned categories and concepts to test situations with unknown objects, and they generalized the categories and concepts. Two horses have also shown impressive long-term memories of 7 and 10 years for object categories and concepts (Hanggi and Ingersoll 2009).

Recently, it was demonstrated that Shetland ponies can distinguish numbers up to 5, by keeping pictures with different numbers of object apart, e.g., different numbers of dots of different sizes in different arrangements. This indicates that they have a concept of numbers. Some of the ponies were able to transfer the “number concept” to different symbols, such as triangles, rectangles, rhombs, and crosses (Gabor and Gerken 2014).

### Social Learning

Finally, the social intelligence hypothesis claims that animals that live in complex social systems face higher cognitive demands. They need to identify group members and deal with conflict. Horses are capable of both. Furthermore, animals would benefit from learning socially, from learning from others, in a complex social setting. For decades researchers had difficulties demonstrating social learning in horses, but now it has been established that horses can learn by observing other horses and from humans (Krueger et al. 2014a; Fig. 4; Schuetz et al. 2016).

An interesting finding has set the stage for further investigations into the topic. It started with the idea that imprinting training, in which humans confronted passive foals with stimuli of different qualities right after birth to decrease their fear, is ineffective. At the age of 3, horses which were imprinted when they were foals reacted as aversively to the presented stimuli as non-imprinted horses. However, grooming the dams for only 10 min a day caused the foals which observed this to show less aversive behavior toward humans (Haupt 2007; Hausberger et al. 2008).

Horses copy the social behavior of other horses, for example, they copy the following of a person, they adapt to the expectations of other horses when crossing a carpet, and they are fearful when others are fearful and confident when others are brave. They can learn to open a feeding box by watching another horse pulling a rope to open it (Krueger et al. 2014a; Fig. 4), and they can learn to open a feedbox by pushing a light switch after watching a familiar person doing it (Schuetz et al. 2016). Interestingly, horses learn from higher-ranking, older horses in their social group (Krueger et al. 2014a), which raises interesting, and so far unanswered, questions about their perception of familiar and unfamiliar persons.

Apart from individual trial and error learning, stimulus and local enhancement have been discussed as the primary social learning mechanism in horses (Krueger et al. 2014a; Schuetz et al. 2016).

**Equine Cognition, Fig. 4** Social learning in horses. (a) shows the situation in which a demonstrator horse (dem) opens a feedbox by pulling a rope. An observer horse (obs) watches the demonstration and the resulting opening of a

drawer with food. (b) depicts the feeding apparatus in detail: (1) is the opening drawer and (2) the rope which has to be pulled and (c) shows the successful observer (Krueger et al. 2014a)

### Effects on the Performance in Cognition Tasks

The performance of horses in cognition tasks may be hampered by environmental, individual, and social factors.

#### Environmental Factors: Housing and Management Conditions

Unsuitable housing and management conditions may cause severe stress and result in altered behavioral responses and cognitive capacities. Housing and management conditions hampered the learning efficiency in a test where horses learned to open a food box by lifting a lid. Horses with stereotypies, which are usually developed under unsuitable housing and management conditions, had poorer performance and also spent less time lying down and sleeping. The reduced resting and sleeping time may have affected the attentional state and therefore the learning efficiency of the horses (Hausberger et al. 2008). In another study, young more stressed, stabled horses took longer to complete standardized initial training on the ground and with a rider than less stressed, pasture-kept horses (Hausberger et al. 2008).

Horses under unsuitable management conditions may show depressive-type behavior, comparable to depressed humans. They “withdraw” into

themselves, and their reaction toward external stimuli, approaching humans, and other horses is altered. When confronted with auditory signals, horses with depressive-type symptoms responded on fewer occasions than control horses, but their low response rate was not reduced further by habituation to the signals. They continued responding to the signals on a low, altered level, while normal horses would stop responding after some repetitions (Rochais et al. 2016).

#### Individual Factors: Prior Experience and Temperament

Some horses may develop preconceptions regarding their participation in cognition tests which may also hamper their performance. Strong preferences for always choosing the same side of a test area (i.e., side biases) have been reported. Side biases may develop from habituation to the experimental procedure, from experiences within the test area, and from the animals’ laterality (for details see below). Apart from side preferences, decisions to go to the opposite side of the arena, when the side first approached was not rewarded, have been reported.

Such learning strategies may be affected by a cognitive bias, i.e., a bias of rating the learning

situation positively (optimistic) or negatively (pessimistic). Horses with a positive cognitive bias tend to judge uncertain situations to be rather pleasant or positive, while horses with a negative cognitive bias judge the same situation to be rather unattractive or negative. Environmental enrichment may cause a positive cognitive bias (Rogers 2010). For example, horses that were housed in single boxes experienced an environmental enrichment by the addition of turnout on pasture, in groups, during the day. This seemed to cause a corresponding positive cognitive bias. All the horses were trained to expect to be rewarded with food in a box when the box was located in specific spots in an arena and to expect no reward when it was placed in different specific spots. When the horses reached the learning criteria and consistently approached the box when it was in the “reward” positions, the box was moved to a neutral position between the trained “reward” and “no reward” positions. The horses that approached the box in the new, neutral, position were considered to have a positive cognitive bias (they had the expectation that the new position would be a “reward” one), and horses that did not approach the box in the new position were considered to have a negative cognitive bias (their expectation was that the new position was a “no reward” one). When the horses had daily turnout, they showed a positive cognitive bias that was not evident when they were fully stabled. However, the researchers suggest that this positive cognitive bias may decrease over time, possibly due to adaptation to the new housing conditions (Rogers 2010; Loeckener et al. 2016).

Animals may acquire a negative cognitive bias when they experience stressful situations while maturing (Rogers 2010). In mice, it has been shown that a strong negative cognitive bias goes along with a left shift in motor laterality, the preference for using a certain leg paw or foot. Recent studies (Marr et al. in progress) indicate that stress in maturing horses causes a left shift in motor laterality and in sensory laterality, i.e., the preference to use sensory organs on a particular side (Rogers 2010). The use of either the left or the right sensory organs and forelimbs appears to result from different responsibilities of the two brain hemispheres that are contralateral connected

to limbs, eyes, and ears. (Nerve tracts from the nasal cavities run to the brain hemispheres on the same side.) The left brain hemisphere is generally considered to be in charge of rational information processing, learning behavior, and responses to routine situations, while the right hemisphere is thought to be responsible for fight or flight reactions, processing emotions and the regulation of endocrine functions and heart rate. Changes in laterality may therefore indicate an altered emotionality and cognitive processing of information intake, i.e., a cognitive bias (Rogers 2010).

The temperament of horses has been shown to affect visual discrimination learning. Prior to a test, horses were assessed on whether they would react more or less emotionally when approaching novel objects. In the ensuing experiment, horses with a higher emotionality assessment required more trials to learn pattern discriminations in a test where yellow and black diagonal stripes indicated the place with a reward in a T-maze test (Hausberger et al. 2008). Similarly, neophobic horses had greater difficulties in learning how to open a feeding apparatus after observing a demonstrator horse (Krueger et al. 2014a). Furthermore, fearful and active Welsh ponies were most successful in learning to avoid a puff of air by jumping a fence, while the least fearful and most sensitive ponies were best in learning how to back up after a tactile or vocal command (Lansade and Simon 2010).

The exposure to particular training strategies may affect the animals' emotional state and their motivation to perform in cognition tests (Hausberger et al. 2008; Rogers 2010). The use of positive reinforcement (adding a pleasant stimulus to enhance the possibility that the behavior is shown more often), negative reinforcement (removal of an unpleasant stimulus to enhance the possibility that the behavior is shown more often), positive punishment (adding an unpleasant stimulus to reduce the possibility that the behavior is shown again), or negative punishment (removal of a pleasant stimulus to reduce the possibility that the behavior is shown again) can result in different emotional states. The animals' motivation to perform may differ depending on whether they experience a positive feeling about something pleasant when positively reinforced, a reduction of

psychological pressure when negatively reinforced, fear of something when being positively punished, or frustration when being negatively punished.

Horses with a chronic stress life history, for example, horses that were repeatedly stressed in previous management and handling, developed more exploratory behavior in a novel object test and showed a higher motivation for training, when they were positively rather than negatively reinforced while learning to be led by humans, stand still while being groomed, traverse an obstacle course, load into a trailer, and pick up their feet (Innes and McBride 2008).

### Individual Factors: Age, Breed, and Sex

Young horses learn faster in social learning tasks in which observer horses can learn how to open a feedbox by observing conspecific or human demonstrators (Krueger et al. 2014a; Schuetz et al. 2016). From a certain age (14 years in one study, see Krueger et al. 2014a), horses failed to learn the task. It has also been reported that only young horses learn to operate a feeding device in an individual learning test. However, it needs to be clarified whether older horses undergo a loss of motivation rather than a decline in cognitive capacities.

The breed may also be a factor in horses' performance in learning experiments. For example, a group of horses picked signs on paper cards to communicate whether they wanted a rug put on in windy and wet weather, a rug taken off when it was warm, or no change. Warmblood horses learned the communication faster than coldblood horses (Mendjell et al. 2016).

Interestingly, in a study which claimed horses' short-term spatial memory for the location of food declines after 10 s, differences between the breeds in behavior at the test waiting area were also reported. Warmblood horses were said to be the most patient, thoroughbred horses became nervous more quickly, and coldblood horses and ponies lost interest quickly and could not be persuaded to participate again once they had refused. Breed differences have also been reported for the performance of horses in a detour task. Ponies from semi-wild management showed an understanding of object permanence, even after a

delay of 10 s. Similar to the donkeys described above, they searched for a food bucket which had been removed from view by detouring around a simple V-shaped barrier. However, Standardbreds which were raised in traditional stabling did not succeed in the task (Baragli and Regolin 2008). A follow-up study is needed to clarify whether the differences in the performance are due to the housing and management conditions rather than to the horses' breed.

### Social Factors: Social Rank and Affiliation

Social transfer of information may be especially dependent on the relationship between observers and demonstrators. Horses appear to learn most readily from higher-ranking, older members of their own group (Krueger et al. 2014a). When horses are confronted with humans in learning tasks, prior experiences with those persons may affect their learning performance, as described above (Schuetz et al. 2016).

### Conclusion

The cognitive capacities of equids were underestimated for decades; in fact, their abilities are in line with the demands of their environment. Horses are extremely social and show highly developed social cognition abilities. They have a well-developed understanding for concepts and categories and readily generalize them to new objects, environments, social contacts, and to their interaction with humans. Humans have used the cognitive skills of horses when training them for centuries, but our understanding of the effect of domestication on these learning capacities is still in its infancy. Many more tests are needed to evaluate the full spectrum of equine cognition.

## Equine Communication

Rachel E. Kristiansen  
Department of Psychology, Sheridan College,  
Sheridan, WY, USA

### Synonyms

Behavior; Horse; Signals.

### Definition

An overview of communicative signals in the domestic horse (*Equus caballus*).

## Introduction

Communication is a social event in which a signal is intended to influence the behavior of the receiver (Seyfarth and Cheney 2003). The ability to recognize other individuals is essential to animals in a social hierarchy, territorial animals, and animals that interact with each other regularly (Scott 2005). A communication system requires (1) the operation of the signals, (2) the sensory and cognitive systems used to receive the signals, and (3) the behavior associated with the signaling. Signals evolve simultaneously with sensory and cognitive systems as these systems determine the signals that are easier to receive, distinguish, and base decisions on (Endler 1993). Animals that possess the sensory equipment necessary to receive the signal make use of all the senses that they are able to use over distances for communication in variable circumstances (Marler 1967).

Signals originally evolved for some other function but have been modified by selection to transmit information (Searcy and Nowicki 2005). Selection has favored signalers who (Seyfarth and Cheney 2003):

- Can exploit the sensory abilities of the receivers
- Accurately signal competitive skill when it is advantageous
- Deceive the receiver when it allows them to win with minimal cost
- Give acoustically different vocalizations in different situations

Simultaneously, selection has favored receivers who (Seyfarth and Cheney 2003):

- Are skilled in extracting information
- Express behavior that makes it easy for them to extract information
- Can rapidly decode signals and respond appropriately
- Can use information to represent their environment

The emission of a communicative signal is dependent on the immediate features of the social environment as well as the history of the

interactions between the signaler and receiver (Seyfarth and Cheney 2003); however, not all communication follows the form of a clear signal followed by a clear response (Manning and Dawkins 1998). Signal generation follows three steps: (1) generate and emit the signal; (2) transmit the signal through a medium, minimizing background noise and interfering signals; and (3) receive and process the signal (Endler 1993). Signal structures are designed to be diverse in order to maintain species specificity and to permit a signaler to elicit unique responses from the receiver (Marler 1967). This allows for the possibility of deception on the part of the signaler.

## Visual Communication

Horses are able to communicate via highly sensitive sensory systems. Horses, unlike humans and nonhuman primates, do not possess a fovea, but instead employ a streak of high density cells to perceive fine detail (Hebel 1976). Horses are dichromats, with visual capabilities resembling those of humans with red-green color deficiencies (Hanggi et al. 2007). Dichromats do not perceive intermediate hues; mixed colors result in either an achromatic hue or a desaturated version of one the colors (Carroll et al. 2001). However, dichromacy in multiple species has provided evidence that having dichromatic vision is more than suitable for solving visual tasks in various habitats, and color deficiencies are compensated for by visual cues such as brightness, hue variation, depth, etc. (Hanggi et al. 2007).

Horses first detect a stimulus based on its size and contrast (Saslow 1999) and highly contrasting and bright colors consistently affect behavior (Hall and Cassaday 2006). Due to the excellent vision in horses, even minor movements that are sudden or unusual can induce arousal. These movements are used to gain attention from conspecifics in threat gestures, such as quick jerks of the head, striking a foreleg on the ground, or rearing. A more subtle form of communication relays the current mood of an animal; a relaxed animal has an elongated posture, whereas an aroused horse has an arch in its back and contracted muscles. In confrontations, horses can

use signals to estimate an opponent's ability to fight (e.g., size). A dominant horse will show an increasing display of threat gestures, while a subordinate horse will either walk away or show a submissive posture (Mills and Nankervis 1999).

## Auditory Communication

Horses' hearing goes to much higher frequencies than that of humans. Therefore, it is reasonable to assume that their vocalizations, while audible to humans, also contain supplemental information inaudible to species with a lower frequency threshold. One example of a horse vocalization is the neigh or whinny. This sound is able to traverse large distances and signifies the presence of an individual, and is often used when a horse is isolated from the group. Nickers seem to encourage socialization with another horse, and are often used by mares towards their foals. Conversely, squeals act as a warning threat to unfamiliar horses or as a reaction to a painful stimulus. When threatened with extreme physical violence, horses issue roars or screams. All of these auditory signals are used in a social context, emphasizing the great importance of access to conspecifics for horses (Mills and Nankervis 1999).

Horses attend to stimuli by pointing their ears (Saslow 2002) and are able to manipulate their pinnae to point directly forward or backward. This may allow an individual to localize sound by orienting the pinnae (Heffner and Heffner 1984). They do not possess good acuity for sound localization, but are able to localize lower frequencies much better than higher frequencies. One study found that horses were able to localize 250 Hz, 500 Hz, and 1 kHz, but could not localize sounds 2 kHz or greater. In fact, they performed at chance levels for tones of 2–25 kHz (Heffner and Heffner 1986).

Vocalizations in feral horses have been hypothesized to encode information about status. Squeals could be associated with physiological ability (via lung capacity or strength of thoracic musculature) and thus provide an indication of the dominance status of an opponent. Dominant stallions emit squeals that are 20% longer than subordinate stallions. In addition, the squeals of these dominant

animals possess high-frequency sounds otherwise absent in the calls of subordinates and they maintain three strong broadband energy wavelengths to the end of the signal, whereas subordinate animals have narrower energy bands towards the end (Rubenstein and Hack 1992).

## Chemical Communication

Chemical signals are found in the form of social odors or pheromones. The horse can obtain chemical information from urine and feces, saliva, skin secretions, and breath. When two horses meet, their greeting involves the investigation of the mouth and nose, flanks, and perineal region. The urine excreted by a mare signals stallions as to whether she is in estrus. Stallions also use feces to declare their presence, and may also be used visually for orientation. Chemoreception allows an individual to identify others, and obtain information on the sex, age, and physiological state of the animal. It provides opportunity for silent alarm signaling, as well as signaling a calm state, and can also be used for navigation and orientation. Finally, chemical signals are useful in the separation of different groups and individuals within a group, as well as promoting the bond between mare and foal (Mills and Nankervis 1999).

The horse possesses a prominent vomeronasal organ, which is more responsive to large species-specific molecules such as pheromones (Saslow 2002). Odors can provide information about identity. In wild horses, stallions are able to distinguish between fecal piles of familiar and novel animals. They showed no response in scent differences of dominant or subordinate horses, but investigated the scent of an unfamiliar stallion twice as long as familiar stallion. If in fact scents are used as a basis to identify individuals, a horse could assess an opponent in a fight by associating the odor of the other horse with previous encounters and outcomes (Rubenstein and Hack 1992).

Certain odors produce a behavior in horses and several other species called flehmen. The flehmen behavior is characterized by a retraction of the upper lip, wrinkling of the nose, and baring of the gums, accompanied by deep breathing. At times the animal may also elevate and extend the

head (Weeks et al. 2002). Flehmen research has mostly been tested through the discrimination of estrus and nonestrus bodily fluids (Weeks et al. 2002). Many researchers believe that the flehmen behavior is most likely associated with sexual behavior rather than novelty (e.g., Christensen et al. 2005). Saslow (2002) reported that stallions age four and up tend to investigate piles of manure with intense sniffing and licking. Mares and geldings, however, show little interest in manure piles. Additionally, a stallion that sniffs its own manure shows a brief period of heightened aggression.

In contrast, Weeks et al. (2002) demonstrated that males and females displayed flehmen equally in response to estrus versus nonestrus stimuli and no effects of age were demonstrated. Horses have also been observed to flehmen in response to a distasteful odor (Saslow 2002). Anderson et al. (1996) discovered that the frequency of flehmen is lower when olfaction is blocked and the number of events associated with flehmen is lower when vision is blocked, indicating that both olfactory and visual cues initiate the flehmen response. Houpt and Guida (1984) support this, stating that stallions are able to use visual and auditory cues to determine if a mare is in estrus and do not rely on olfactory stimuli.

## Tactile Communication

Tactile stimulation is used in most species to provide relaxation and form or enhance relational bonds. Mutual grooming episodes may be used as a measure of social bonding (Crowell-Davis et al. 1987) and can also produce a pleasing response at certain parts of the body (Saslow 2002). Horses are very sensitive to tactile stimulation. Intraspecifically, they employ touch during mutual grooming, where a pair of horses will nibble each other's backs, manes, and limbs for a short period of time. This behavior is increased during the molt cycle and times when external parasites are prevalent (Mills and Nankervis 1999). For horse owners, tactile stimulation is used to communicate with their animals (Saslow 2002). The primary nonaversive stimuli used in training are tactile (e.g., pressure against the sides, shifting weight, lifting of reins), although aversive

tactile stimuli such as whips and spurs are also employed (Dougherty and Lewis 1993). Inexperienced riders may inadvertently deliver irrelevant tactile signals, thereby failing to teach the horse to discriminate meaningful signals (Saslow 2002).

Spier et al. (2004) demonstrated that foals that were handled neonatally were significantly more inclined to allow the researcher to pick up their back feet and handle their limbs at the age of 3 months compared to foals that had not been handled neonatally. They also observed that the mares of handled foals seemed more relaxed during the second conditioning session. Handling techniques developed by Miller (1991) include full-body rubbing, picking up each hoof, slapping each hoof until the foal ceases to respond, rub the inside of the ears, mouth, and nostrils, rub the foal with a plastic bag, and spray water near and on the foal. The goals of tactile conditioning are: (1) bonding with humans, (2) desensitization to certain stimuli, (3) sensitization to certain stimuli, and (4) decreasing the fear response (Miller 1991).

## Conclusion

Overall, communication in horses can be very complex, and may employ more than one type of sensory system at a time. Socialization depends on a horse's ability to emit signals, as well as detect and process them. From birth, foals learn the importance of such communicative signals such as the scent of its mare, meanings of different vocalizations and body postures, and grooming from others. These learned signals are vitally important to the later survival and reproductive success of the adult horse and are also important to the relationship between horses and humans. Equine sensory systems are extremely sensitive and influence the behavior of the horse in response to stimuli. Their vision picks up fine detail with the visual streak, despite lack of a fovea, but they see objects on the ground easier than raised objects. Horse hearing has a significantly higher frequency threshold compared to humans, though they have difficulty localizing sounds about 2 kHz. Olfaction is used widely by

the horse for individual identification and utilizes the behavior flehmen during scent investigation. Touch is used in horses from birth, and is used in adulthood primarily for mutual grooming. Domestic horses show reduced heart rate in response to human tactile stimulation. Horse behavior ranges from simple to complex, but every behavior along the continuum is dependent on these advanced sensory systems. Study of these systems and behavioral processes will greatly enhance human understanding of the horse and the human-horse relationship.

## Definition

Feeding and nutrition of horses

## Introduction

Horses have been incorporated into the lives of humans throughout history and cultures in diverse roles and purposes for centuries. Horses have evolved from primarily grass-dwelling creatures (Muller 2012), and the equine diet is unique and dependent upon the role and use of the horse. The domestication of horses, as well as the popularity of equestrian sports, has led to a change in dietary standards for horses (Manso Filho et al. 2019). Although domestication has changed the foraging habits and equine diet, horses have small stomachs that cannot intake large amounts of concentrated feed and supplements at one time since they only have a capacity of approximately 2–4 gallons (Williams 2004). The implementation of equine nutrition varies across disciplines and geographic regions (Mastellar et al. 2017), and it is essential to understand proper feed and nutrition for horses as individuals with unique needs.

Nutrition is a vital component of equine care, and without appropriate management, various health problems can occur in horses (Mastellar et al. 2017). Maintaining the proper equine diet is essential for caregivers of horses, as improper nutrition can lead to a variety of health issues, such as metabolic diseases or colic (Parker et al. 2018). It is essential that the diet of the horse is related to its role, and proper nutrition supports the lifestyle of the horse. However, whereas the diet of a wild horse consists of forage or roughage, the diets for domesticated horses should consist of roughage, as well as concentrated feeds and supplements, that provides proper care and nutrition that is aligned with their lifestyle. A senior horse requires a specific diet for age and nutrition compared to the needs of a younger horse used in various competitions, such as racing, endurance, or show jumping. It is essential that the diet of the horse is related to its work and proper nutrition supports the lifestyle of the horse. Overall, the equine diet for domesticated horses consists of

roughage and various types of concentrated feed, which is dependent upon factors such as age, lifestyle, special needs, and work. Some horses are also provided additive supplements in addition to their regular equine diet for a variety of healthcare and lifestyle accommodations.

## Roughage

Although a domesticated horse has a greater range of available food than a wild horse, it is essential to remember that it is still a grazing animal (Vogel 1995). Roughage, including grazing and consumption of forage, hay, and hay-related products, is an essential part of equine diet and nutrition, which horses should have access to for most of the day. Diets consisting of low rations of roughage have contributed to an increase of digestive upsets and colic in horses, as well as increase in dental treatments for horses (Muller 2012). Digestibility is also a key factor that affects the value of feeding forage to horses (Hansen and Lawrence 2017). Horses are also known to be more selective grazers in comparison with other livestock, and research has demonstrated preferences for different types of roughage based on geographical location (Martinson et al. 2016). It is also essential to consider the seasonal nutritional value of roughage and hay for horses. The nutrients in forage vary greatly with the maturity of grasses, environmental conditions, fertilization, and management (Williams 2004). Quality hay for horses should be leafy, fine-stemmed, and green in color, as well as free of dust and mold, in order to have the best nutritional value (Hill 2007).

There are several hay varieties available for horses that are dependent upon type, cutting, and geographical location. Hay varieties include alfalfa, birdsfoot trefoil, red clover, orchard grass, timothy, and brome (Hill 2007). Alfalfa tends to be a popular choice for hay, as it is a good mineral source and more nutritious due to its large leaves (Vogel 1995). Also, each of these types of hay should be cut at specific time as roughage that is harvested at late maturity consists of a lower nutritional value and must be fed to horses in higher amounts (Muller 2012).

Generally, a mixed grass type of hay, such as meadow hay, is suitable for most horses, which is made in a permanent pasture (Vogel 1995). However, since hay can vary in nutritional quality, horse owners should also test hay before a large purchase to be sure it meets the needs of the equine diet. Additionally, hay must be stored properly to avoid retention of moisture, which causes mold and can lead to respiratory issues and illnesses in horses.

Other fibrous foods may also be part of the roughage equine diet. Silage, a compacted and fermented grass feed, must be wrapped and stored carefully to avoid causing botulism and other illnesses in horses (Vogel 1995). Straw can be chopped into tiny pieces to make chaff for horses, and grass can be vacuum packed for horses, which provides more nutritional value than hay (Vogel 1995).

## Feeds: Parts of a Balanced Diet

Although a horse should be fed mostly roughage, grass and hay usually cannot supply the energy required for work (Vogel 1995). Each horse is an individual and requires a unique, balanced diet. Effective planning for the equine diet includes providing energy through a balance of food and work based on the individual horse. A horse that does little or no work may require a diet consistently mostly of roughage, but the diet of a horse that engages in two or more hours of hard work, including galloping or competing, must include approximately 45% of concentrated feed (Vogel 1995). A vast array of concentrated feeds is available to meet the equine diet and nutrition of horses according to breed, work, special needs, and age. The feeds are part of a balanced diet for horses that includes protein, carbohydrates, fat, vitamins, and minerals, as well as water (Vogel 1995).

Protein is important as the building blocks of muscles. Soybean meal and alfalfa are good sources of protein and may be used for higher protein consumption in lactating mares and growing foals (Williams 2004). Most adult horses require 8–10% protein in their feed ration.

Carbohydrates are the main energy source used in most feeds (Williams 2004) and are also an essential part of the horse's diet. Carbohydrates consist of simple sugars, starches, and cellulose, but many horses, particularly those with metabolic issues, can benefit from a diet without sugar or molasses (Hill 2007).

Fats are associated with healthy coats for horses and are necessary for metabolic functions (Hill 2007) and can be added to increase the energy density in the horse's diet (Williams 2004). Most concentrated feeds have a 2–6% of fat, but some higher fat feeds fill contain 10–12% of fat (Williams 2004).

Horses typically have adequate amounts of vitamins in their diet if they are consuming fresh green, leafy forages (Williams 2004). Vitamin E is found in leafy greens, and Vitamin D is obtained through sunlight. Horses that are provided with fresh fruits and vegetables are receiving Vitamin C.

Minerals are required in the equine diet for electrolytes, body structure, nerve conduction, and muscle contraction (Williams 2004). Macro-minerals, such as calcium, sodium, magnesium, and potassium, are required daily in small amounts (Williams 2004). Minerals, such as salt, are absorbed by horses when grazing and through salt lick blots (Hill 2007; Vogel 1995).

There are a variety of concentrated feeds available to meet the diverse nutritional needs of domesticated horses consistent with their age, work, and lifestyle. Concentrated feeds can be loose or processed into pellets or grains, which provide a balance of nutrients (Vogel 1995). One of the most popular types of feed is oats, which has a low-energy content. Feed is also available in the form of pellets, which is manufactured to suit different horses, but coarse feed mix is more appetizing and takes longer to eat and digest (Vogel 1995). Barley, oats, and corn are also included in concentrated feeds for horses. These types of feed are lower in fiber and higher in energy than roughages (Hill 2007), but flaked corn is processed further so that it provides less energy (Vogel 1995).

Another popular feed option for horses is alfalfa pellets, which consists of a strong

concentration of vitamins and minerals similar to grass. Additionally, various forms of beets, which is rich in protein and energy, can be part of concentrated feed, including beet pulp, beet cubes, and soaked beet. It is essential that each form of beet pulp is soaked in water as it expands rapidly and may cause the horse to choke or colic. Beet-related feeds are also an excellent source of fiber for horses, and some horse owners add beet products as a supplement to concentrate feeds dependent upon individual horse's needs. Additionally, supplements and treats can also be included as part of the equine diet.

## Supplements

The equine market includes a wide variety of supplements to aid equine diet and nutrition. Supplements are used for a variety of purposes, including weight management, parasite control, joint support, and hoof and coat enhancement. Supplements can be provided to horses in different forms, such as salt lick blocks and rations. It is essential that horse owners clearly understand the needs of their horses, as well as the purpose and effects of supplements. If a horse owner is unsure of which supplements will be necessary or effective, a veterinarian should be consulted for guidance.

Various oils can also be included as supplements in the equine diet and mixed with feed. Oils, such as corn or vegetable oil, are a rich source of energy and can be added to the diet of competition horses to supply their energy needs (Vogel 1995). Additionally, oils, such as cod-liver oil, are also a good source of calories for weight gain, as well as contributory to a healthy skin and hair coat (Hill 2007). Linseed is also a supplement used to help produce a shiny coat, but the seeds can be toxic for horses if not boiled for many hours and prepared properly for horses (Vogel 1995).

In addition to oils, molasses is also a popular supplement for horses. Molasses are a common ingredient in treats for horses, as well as some beet pulp feeds. However, although it is a palpable supplement, horses with metabolic issues should

have a reduced intake of molasses so as not to incur digestive or laminitis issues. When not being used as a supplement, molasses can also be mixed directly with medicines and put directly into the horse's mouth (Vogel 1995).

When many people think about what horses eat, carrots and apples are common responses. Although these roots and fruits are ideal healthy treats for most horses, they must be cut lengthwise as opposed to circles to prevent choking (Vogel 1995). Carrots may be fed in larger quantities but do not have great nutritional value (Vogel 1995).

## Water

Water, naturally, is an essential part of the equine diet. Water is necessary for horses to avoid colic, dehydration, and death, and the average horse will intake 5–10 gallons of water each day (Swinker 2014). Horses should have free access to water at all times. Water must be clean and unpolluted (Vogel 1995), as well as clear of algae and insects, such as mosquitoes, which carry diseases that can be fatal to horses. Horses grazing in a pasture may also have access to natural water sources, such as a clean running stream or creek. Horses grazing in pastures are also able to consume water through the intake of grasses, which is decreased during the winter months when the equine diet consists of roughage (Swinker 2014). Some horses are also less active during the winter months. Therefore, it is essential to be more mindful of the horse's water intake during winter months and to consistently check that water buckets and troughs are full, clean, and unfrozen.

## Conclusion

Equine diet and nutrition will continue to develop with new knowledge, technology, and the use of horses. Research has demonstrated that knowledge of equine nutrition is not always reflected in management practices and that the understanding and application of equine nutrition concepts can be improved (Mastellar et al. 2017).

Additionally, each horse is a unique individual and requires a feeding regimen based on their age, breed, geographic region, special needs, and work.

## Definition

Movement used by equine species to traverse their environment.

Horses belong to the order Perissodactyla, a group of odd-toed ungulate mammals, which are characterized by the enlargement of the third digit on each extremity (Bowling and Ruvinsky 2000). Horses fall under the family Equidae and the genus *Equus*. It is likely that horses, donkeys, and zebras all evolved in North America and spread when the Bering land bridge was open into Africa, Asia, and Europe (Bowling and Ruvinsky 2000). Why equids eventually became extinct in North America is unknown, but the last of them was perhaps exterminated by the first human inhabitants some 12,000 years ago (Bowling and Ruvinsky 2000). Wild horses survived into historic times. Unfortunately, both the Tarpan (*E. ferus ferus*) and the Przewalski horse (*E. ferus przewalskii*) are now either extinct or critically endangered. The extinction of the Tarpan came about when the last wild Tarpan was killed in December 1879 in Ukraine and the last living purebred Tarpan living in the Moscow Zoo passed in the late 1880s (Bowling and Ruvinsky 2000).

Horses domesticated around 6000 years ago in the steppes area of Russia and Ukraine gave rise to

the modern-day horse (*E. ferus caballus*) (Bowling and Ruvinsky 2000). The earliest evidence of domestication came from an excavated settlement in southern Ukraine which dated back to 4200–3800 BC (Bowling and Ruvinsky 2000). Horses are recognizable by the long-haired tail, a mane that is both long and thick and tends to fall on one side, and an elongated snout. The metacarpus is short compared with the metatarsus so the horses' hindlegs are longer than their forelegs (Bowling and Ruvinsky 2000). Horses have played a crucial role in the expedition of social progress. Horses have contributed to military campaigns, the development of transport systems, and the improvement of agriculture. Even with the advent of modern technology, the use of horses in sports, including racing, is wildly popular. The speed of the horse has hardly increased under traditional artificial selection methods since the nineteenth century suggesting the horse may have reached its physiological speed limit through natural selection and evolutionary pressures (Bowling and Ruvinsky 2000).

## Gait Patterns

Equine locomotion is divided into natural and acquired gaits, each of which has their own sub-classifications. Natural gait patterns include walk, trot, canter, and gallop, which are differentiated by footfall patterns, speed, and gait beats. It is classically accepted to describe gait patterns starting with the footfall of the left hind limb (Hildebrand 1989). The walk pattern is traditionally categorized as a lateral sequence lateral couplet (i.e., left hindlimb to left forelimb, right hindlimb, right forelimb; Fig. 1). It is considered a four-beat gait, which means each foot strikes the ground at a different moment in time, but two feet are always in contact with the ground (Ball 2006). The trot is a two-beat gait where the limbs work as diagonal pairs, the left hindlimb and right forelimb move together, and the right hind limb and the left forelimb move together. Canter is a three-beat gait which sees one diagonal pair moving at the same time, while the opposite diagonals move independently. For example, if the left hind limb

**Equine Locomotion, Fig. 1** “Hildebrand” plot displaying phase against hindlimb duty factor collected during quadrupedal walking in equines ( $n =$  three species)

strikes independently, the right hind limb and left forelimb will strike together next, followed by the right forelimb. This is called a right lead since the right forelimb is moving independently. A left lead canter would be the same sequence on the other side. The gallop is a four-beat gait, similar to canter, except diagonals do not strike together (Ball 2006). Two types of gallops exist, a rotary gallop where the feet fall in a circular pattern (left hindlimb, right hindlimb, right forelimb, and left forelimb) and a transverse gallop in which the weight is transferred on a diagonal axis (i.e., left hindlimb, right hindlimb, left forelimb, and right forelimb). Both types of gallops have two forms, clockwise and counterclockwise for rotary, and left and right lead for transverse (Leach et al. 1984) (Fig. 2).

Additional gait variants are possible, but not universal across breeds. The ability to perform these additional gaits properly has been linked to a gene mutation of the *DMRT3* gene affecting spinal neurons. The *DMRT3* gene was found to play a pivotal role in the development of spinal circuits that control strides and limb movements. The mutation allows a greater variety of gait patterns to emerge, by coordinating left and right limb movement, as well as forelimb and hind

limb movement. Icelandic horses are well known for their characteristic gait pattern, known as Tölt, and have a high heritability of the genetic mutation: 0.6–0.73 (Andersson et al. 2012).

Although gaits are distinctly named and classified, the classifications are varied and difficult to properly differentiate. The different gaits are seen more as a continuous spectrum rather than different set points of motion, and boundaries set to differentiate the gaits are somewhat arbitrary. They tend to vary heavily based on the species of the horse, rather than by the general movement of the limbs (Hildebrand 1965).

## Limb Loading

The study of the limb loading (i.e., the external forces acting on the limbs) has increased practical detection of horse lameness (abnormal gait or stance due to a locomotor dysfunction) and has thus enabled better treatment of these animals (Bobbert et al. 2007). Several methods have been developed to study the limb loading forces during various gaits, such as force plates in the ground, treadmills with force sensors under the support structure, instrumented horse shoes that capture the work output, and an indirect method where force vectors are calculated based off of the kinematics of the horse during gait. Each of these techniques presents their own advantages and disadvantages. Ground force plates can measure the strike in its full force, with several force vectors analyzed, but are unable to measure several steps in sequence. Data is also harder to gather since the hoof strike has to occur exactly on the plate and horses have a natural tendency to avoid the plates (Bobbert et al. 2007). Treadmills are able to capture several strides in sequence, but their measurements are sometimes incomplete, and the horse has to be habituated to treadmill walking (Bobbert et al. 2007). Horseshoes with embedded transducers are able to measure several strides in series with no training of the horse; but have limitations in the data they gather, are sensitive to shock, and weigh more than natural shoes, thereby slightly altering gait (Bobbert et al. 2007). The method based on kinematics works by recording and

**Equine Locomotion, Fig. 2** Foot fall diagram representing the two types of gallops found in horses. *LH* left hindlimb, *LF* left forelimb, *RH* right hindlimb, *RF* right forelimb

measuring the movements with tracers on the limbs, with the assumption that the distal limb acts as a linear spring with a consistent stiffness. In reality, each horse differs slightly in regard to the spring like capacity of their musculoskeletal system, with one research group listing ranges as great as  $101\text{--}156\text{ N}\cdot\text{kg}^{-1}\cdot\text{m}^{-1}$ . This means that to accurately measure ground forces via kinematics requires some calibration of the tendon spring capacity before accurate results can be obtained, but once calibrated, can provide accurate measurements over sequential strides (Bobbert et al. 2007).

Merkens and Schamhardt (2010) analyzed kinematics and the ground reaction forces occurring in the forelimb and hind limbs of horses during different gait patterns, with ground plate and kinematic analysis assisted by the presence of photodiodes (tracers) on the limbs. They found that the ground impact occurring in both walk and trot were similar in each limb, but that overall, the forelimbs had a higher ground force reaction than the hind limbs. Further research into this showed that the forelimbs carry approximately 60% of the body weight at rest and have greater vertical forces when moving (Merkens and Schamhardt 2010) (Fig. 3). However, the hindlimbs

experience greater horizontal forces during locomotion, as they generate more of the propulsion for the animal (Payne et al. 2005).

During locomotion high external forces act to hyperextend the fetlock joint in horses. Hyperextension of the fetlock joint (Fig. 4) causes high levels of stress in the *m. interosseus medius* (suspensory ligament) and deep digital flexor and superficial digital flexor tendons. The high forces get built up within the tendons as stored potential energy, allowing the limb to act in a spring-like manner, releasing the stored energy as kinetic energy for high-efficiency gaits. However, the high stresses in these tendons increase with speed, and thus, the tendons become more prone to injury with increased speeds (Harrison et al. 2010).

## Kinematics

The kinematics of horse movement is largely defined by the specialized anatomy of the joints in their lower extremity. While horses share similar skeletal arrangements to other mammals due to common descent, the evolution of their bones and joints has adapted them for efficient gait

**Equine Locomotion,**

**Fig. 3** Force plate recording of the horizontal (red) and vertical (blue) ground reaction forces of the right fore and hind limb at walk (top panel) and trot (bottom panel). Data from Merkens and Schamart (2010)

**Equine Locomotion,**

**Fig. 4** Forelimb (left) and hind limb (right) joints of the horse mentioned in text

patterns. Starting distally (Fig. 4), the equivalent of the distal interphalangeal joint is the coffin joint, located directly above the hoof (Budras et al. 2012). This joint is classified as both a hinge and saddle joint, due to the unique articulation of the bones' joint surfaces. The fetlock joint is a hinge joint located proximal to the coffin joint and corresponds to the human metacarpophalangeal joint. Most proximally is the

carpal joint, also known as the hock joint in the hind limbs. In horses, this joint resembles the human equivalent of the elbow or knee. Altogether, these joints allow for flexion and extension of the hoof, pastern, and canon (Holmström et al. 1990).

The coffin joint absorbs energy (negative work) received into the limb during the initial strike with the ground, and a large burst of

positive work (generated by the musculoskeletal system) extends the joint during push off. The fetlock joint produces the largest burst of positive energy of the three lower joints mentioned. The positive work occurs during the swing of the contralateral limb, originating from stored energy across the musculotendinous structures travelling through the joint (Colborne et al. 2010). The main negative work occurring in this joint is in the early stance, as it is flexed against extensors. There are also small periods of both positive and negative work occurring in the joint while in mid-stance. The carpal joint's main function is negative work, much like the human knee. In early stance the carpal joint works against a flexor moment and then oscillates to work against an extensor moment in the end stance, which facilitates transition to the swing phase (Colborne et al. 2010).

Horses are most often used for riding, driving, or working, all of which are activities that increase the workload in the limbs and can thereby alter the kinematics of locomotion. To adjust to the added weight, work horses increase the time spent in stance phase and increase extension in the fetlock joint to optimize the stability and work output. In driving conditions (pulling a carriage or sleigh), horses at trot increase the range of motion of their carpal, fetlock, and elbow joints (Miró et al. 2006). The greatest increase in range is in extension of the fetlock joints of the forelimbs, which occurs with no significant change in the ground forces through the limb. This indicates that there may be a compensatory measure to adapt to the added weight or stress. In addition to the increase in the joint angles, there are significant decreases in the speed, stride length, and swing duration in both walk and trot when in driving conditions (Miró et al. 2006).

Correlations between angles of joints and performance in show and jump have also been found. Larger hock angles are found in elite performers, indicating that smaller hock angles might lead to more injury and decreased ability to properly perform at higher levels due to inability to support their weight when stepping under themselves (Holmström et al. 1990). Similarly, a correlation was also found between increased performance in show and dressage horses and the slope of the

scapula. Elite dressage performance horses had greater inclinations of their scapulae, allowing for better performance of gaits, whereas “underachieving” horses had a straighter scapular slope (Holmström et al. 1990).

A longitudinal study done over 15 years with more than 5000 horses indicated that all of these variables are not only greatly affected by the gait pattern and velocity but also by the age and sex of the animal. When comparing groups differentiated by age and sex for length versus velocity, it was found that these features share a positive linear correlation; as velocity increased, stride length increased. With this study, it was noted that older males had the longest stride per velocity, and young females had the shortest strides per velocity. This also showed that inversely young females had the highest stride frequency to make up for the decreased length, and older male horses had the lowest stride frequency (Seder and Vickery 2003).

## Energetics

The size and speed of large running mammals require substantial energetic demands. Among large mammals, horses consume less metabolic energy than expected based on body mass even when moving at relatively fast speeds (Butcher et al. 2009). Much of this extra locomotor capacity may result from the effective utilization of elastic strain energy (Butcher et al. 2009). Muscles and tendons serve as springs, alternately storing and releasing elastic strain energy as the animals bounce along at a constant speed (Heglund and Taylor 1988). Strain energy recovery is most effective when animals use bouncing gaits at faster running speeds (Butcher et al. 2009).

Tendon strain energy storage is defined as the energy that can be stored within a muscle-tendon unit complex as that muscle-tendon complex is elongated during an eccentric contraction, that is, when the limb acts as a strut and the animal's momentum loads the limb (Butcher et al. 2009). Energetically favorable use of strain energy requires that tendons allow strain energy storage under a given load and that the muscles of these tendons produce adequate resisting force in a

metabolically economical manner (Butcher et al. 2009). Short fibered, multipennate muscles with long tendons are specialized for economical high force and enhanced elastic energy storage (Butcher et al. 2009; Dutto et al. 2006). For force production alone, short, pennate fibers are the most metabolically economical organization for muscle. High force is provided by a large number of sarcomeres in parallel (multipennate architecture) while the volume of active muscle, a reliable predictor of metabolic cost, is minimized via short fibers with fewer sarcomeres in series (Butcher et al. 2009). Lengthening contractions of slow, multipennate fibers result in high force production with relatively large tendon strains and substantial strain energy storage (Butcher et al. 2009). This is especially evident during trotting, where moderate trotting can store mechanical work by tendon elastic strain (Dutto et al. 2006). Active eccentric contraction results in substantial force enhancement while maintaining a relatively lower metabolic energy investment (Butcher et al. 2009). Short, multipennate muscle fibers facilitate this function because a small absolute stretch of the muscle results in force enhancement while limiting the number of sarcomeres that must be activated (Butcher et al. 2009). Short-fibered pennate muscles with long, thin tendons have been shown to provide economical high force production and enhanced elastic energy savings in the bouncing gaits, reducing the metabolic cost of locomotion in horses (Butcher et al. 2009; Dutto et al. 2006).

The cost of locomotion in horses is determined primarily by two factors: the cost of activation of muscle determined by pumping calcium into the sarcoplasmic reticulum and the cost of force generation determined by cross-bridge cycling (Heglund and Taylor 1988). Both costs increase directly with increasing stride frequency. The cost of activation will vary directly with stride frequencies because the muscles will be turned “on” and “off” once per stride necessarily increasing with higher stride frequencies. The cost of force generation will also vary directly with stride frequency. The same mass-specific force will have to be generated and decay once per stride. The greater frequency requires increased rates of force

generation and decay which in turn requires faster rates of cross-bridge cycling (Heglund and Taylor 1988). Thus, the energetic cost of locomotion in equine species at a given speed is almost directly proportional to the stride frequency (Heglund and Taylor 1988).

Stride frequency increases nearly linearly with increasing speed during a trot in all quadrupeds; however, energy cost per stride also increases with speed (Heglund and Taylor 1988). The metabolic rate when locomoting increases when the length of time the hoof is in contact with the ground decreases (Wickler et al. 2003). The increase in energy cost per stride with increasing speed may be related to differences in mechanical advantage of the limb muscles. Changing mechanical advantage requires higher muscle forces for the same ground force reaction as stride length increases both in the trot and in the gallop (Heglund and Taylor 1988). In both a trot and a gallop, stride length during the time the foot is in contact with the ground increases with speed. In other words, when traveling at greater speeds the length of each stride the horse takes increases, yet the amount of time the hoof is in contact with the ground does not increase. Thus, the limb excursion angle increases with increasing stride length (Heglund and Taylor 1988). This increase will change the average mechanical advantage between the limb and muscles and the ground and will require that a greater average force be developed (Heglund and Taylor 1988). In the trot, the increase in stride frequency nearly matches the increase in the rate of energy consumption. Most of the increase in cost with speed could be explained by the higher costs associated with higher stride frequencies. The remainder can be explained by increasing average muscle force associated with increasing stride length (Heglund and Taylor 1988). In a gallop, the stride frequency only increases by about 10% for every twofold increase in speed. Thus, the increase in speed is necessarily driven by an increase in stride length. Therefore, the mechanical advantage will change more dramatically for the higher average muscle force this entails (Heglund and Taylor 1988).

The trot-gallop transition is defined as the transition point between the maximum trotting

speed and the minimum galloping speed (Wickler et al. 2003). The stride frequency is the same whether animals trot or gallop at this speed (Heglund and Taylor 1988). If stride frequency is the same, then what determines gait transition? Several theories have been proposed and substantiated yet the prevailing two hypotheses for gait transition revolve around the metabolic economy and force-triggered transitions (Wickler et al. 2003). Horses transition from walking to trotting at an energetically optimal transition speed (Wickler et al. 2003). Likewise, horses transition from a trot to a gallop when it is energetically favorable, but see Granatosky et al. (2018). However, horses will also transition gaits when it is energetically unfavorable to do so when carrying a given load. Therefore, forces acting on the bones have been identified as a potential trigger for the trot–gallop transition (Wickler et al. 2003). As complex as gait transitions may be, it has been observed that terrestrial animals exhibit a clear preference for the speeds and frequencies used within each gait in nature (Heglund and Taylor 1988). Preferred speeds fall in the middle of the speed range within each gait, and at the minimum sustained galloping speed, the gallop is more economical than the trot (Wickler et al. 2003).

One of the major evolutionary adaptations of survival for the wild equid is a swift retreat from threatening circumstances (Back and Clayton 2013). Consequently, the horse has an efficient locomotor system designed to move a relatively large mass with great speed and endurance. Animals that are highly adapted for aerobic endurance, such as horses and dogs, have much greater speed ranges than less aerobic animals, such as goats and cattle (Heglund and Taylor 1988). Horses not only have high intramuscular stores of glycogen for quick bursts of energy but also have large intramuscular concentrations of mitochondria for sustained aerobic metabolism (Back and Clayton 2013). Large intramuscular energy stores combined with the ability to increase oxygen-carrying capacity through splenic contraction allow horses to have a high aerobic capacity for sustained locomotion (Back and Clayton 2013).

## Jumping

Jumping plays a major role in many equestrian sports. Equine jumping is an asymmetrical activity with three phases: the approach, the jump stride, and the move off (Clayton 1989; Meershoek et al. 2001). The stride before the jump stride is referred to as the approach stride. Normally, the horse approaches the object to be jumped in a transverse canter or gallop in which the leading forelimb and hindlimb pair is ipsilateral. The jump stride is the stride in which the horse jumps and is subdivided into the take-off, jump suspension, and landing. The take-off is the period from impact of the first hindlimb to liftoff of the last hindlimb in the jump stride. During the take-off, both hindlimbs function similarly to the single take off leg of bipeds. Therefore, take-off may be considered the stance phases for the hindlimbs. The jump suspension is the period from lift off of the last hindlimb at take-off to the impact of the first forelimb at landing. The landing is defined as the period from the impact of the first forelimb after the jump suspension to the next impact of the trailing hindlimb (Clayton 1989). During landing, the leading forelimb is placed down later and more forward than the trailing forelimb. This placement variance results in a difference in tendon loading between the forelimbs, with the flexor tendons in the trailing forelimb more loaded than in the leading forelimb. In addition, the extensor tendon in the leading forelimb is also loaded (Meershoek et al. 2001). The move-off is the period when the transition to forward movement is completed, balance is regained, and the normal stride pattern is reestablished. The strides following the jump stride are called move-off strides (Clayton 1989).

## Bioinspired Robotics

Knowledge of equine locomotion has spurred innovation in the field of robotics. In fact, several biomimetic robots have been designed using the principles of equine limbs and joints. One such model defines five key elements of the equine limb (effective leg length, leg kinematics, limb mass distribution, actuator power, and elastic

energy recovery) as the determinants of the animals' agile and powerful locomotion, and then applies these elements to a robotic leg prototype (Garcia et al. 2011). Another similar model relies on the analysis of equine joint trajectories while walking, trotting, and galloping to describe a set of four kinematic Motion Primitives that are used to generate viable and stable gaits in a quadruped robot (Moro et al. 2013). Conversely, a dissimilar model uses the mechanical stiffness of a dual-spring structure inspired by an equine distal forelimb (low-stiffness spring at touchdown and high-stiffness spring during the support phase) to improve the gait stability of a hydraulic quadruped robot when it travels over uneven terrain (Park et al. 2015). However, the impact of understanding equine locomotion in the realm of robotics is not just limited to biomimetic robots. Exotendons have also been developed based on the polyarticular elastic mechanisms of equine locomotion and can be used to aid in human locomotion. These unpowered assistive devices can significantly reduce the muscle forces as well as the metabolic energy needed for walking and may even allow for the independent movement of human patients with substantial deficits in muscle function (van den Bogert 2003).

## Conclusion

The equines share common structures to humans that have evolved differently over time to allow them specialized movement and gait patterns. These specializations allow horses to travel at high speeds efficiently due to energy storage within the spring like musculotendinous structures of their distal limbs and high-power output from the proximal limbs. Information about the gait patterns, kinematics, limb loading, and energetics of horses can be used to influence human advancement in bioinspired robotics.

### Definition

*Umwelt.* J. von Uexküll used the term “Umwelt” (meaning subjective universe) to characterize the particular perceptual world of a species or even an individual. The subject’s Umwelt is divided into two parts, the Merkwelt and the Wirkwelt, both forming a coherent entity. Merkwelt (“perceptual world”) refers to everything a subject perceives. Wirkwelt (“active world”) refers to everything a subject does. To be perceived by a subject, objects have to possess a feature (Merkmal) that matches a subject’s receptor. The perceived stimulus is then processed in the Merkgorgan (“sense organ”), for example, the brain, where a meaning is attributed to each stimulus. This meaning can change depending on the context or the subject’s internal state. Thus, a stimulus can have different meanings to the subject. We thus have to keep in mind that the horse’s perceptual world differs strikingly from that of humans (Leblanc 2013).

### Introduction

Horses have adapted to natural conditions where they live mostly in groups in large open spaces. They spend most of their time grazing or eating a

variety of diverse plants or fruits. Although horses have disappeared from the wild, Przewalski horses have reproduced in captivity and have been successfully reintroduced in various areas from where they originated. Escaped or released domestic horses have successfully expanded in various parts of the world such as North America, Australia, and even Namibia. These observations show that domestic or captive-raised horses retain some of the adaptations arising from evolutionary pressures. Being able to survive in a given environment depends fundamentally on perceptual abilities, whether to escape predators, choose the right food, or memorize where resources can be found. They must thus be able to detect constantly danger while foraging which is their major activity (Waring 2003). They must also be able to associate plant characteristics (shape, odor, flavor, energy content) with immediate or delayed consequences. Horses also have a clear social organization that relies upon both social affinities and hierarchy and ensures restricted energy expenditure and risks. Socialization in stable groups occurs through ritualized communication signals that prevent aggression escalation (e.g., Waring 2003; Fureix et al. 2012a). Communication signals may thus be very subtle and involve individual identity, group membership, and/or social status. Perceiving these signals, which can be unimodal (e.g., auditory) or multimodal (e.g., visual and auditory), is therefore an important part of the individual’s ability to be part of a well-functioning group (e.g., Lemasson et al. 2009; Proops et al. 2009).

Information on the perceptual world of horses arises from two major fields of study: (1) anatomical studies that inform us on the morphology of sensory systems, from the peripheral sensory organs (e.g., ear) to central areas (e.g., primary auditory cortex) where the brain processes sensory information, and (2) behavioral studies where the horse’s reactions and perceptions of stimuli are assessed. Both approaches have advantages and limits. Anatomical data give us an idea of how the animal may perceive stimuli (e.g., presence of typical cells and their density) where any inference is biased by the human perceptual system. Moreover, the properties perceived are not necessarily

the “real” properties of the objects detected: the brain constructs perception on the basis of the information provided by the sensory organs but also its own memories and characteristics. For example, kittens raised in a uniform environment are unable to perceive stripes and will perceive something else (Hubel and Wiesel 1963). Behavioral reactions are an expression of perception but individuals may not react just because they lack attention or motivation, especially in cases where experiments involve conditioning learning. Conditioning learning is the most used procedure where individuals are trained to respond to one type of stimulus through positive reinforcement (e.g., if a circle appears on a screen) and to neglect others (e.g., if a triangle appears on a screen). Appropriate responses guarantee that the animal has discriminated, and thus perceived, the two types of stimuli. Stimuli properties can be modified to become very close which can inform on the limits of perception (i.e., acuity).

## Visual Perception

This is the most studied modality, probably because it seems the easiest to test and horses react clearly to visual communication signals, novel or moving stimuli (e.g., Waring 2003). The eyes of horses are very large (more than 7 times the size of a human eye) and the

circumference of the retina is greater than that of most mammals, which means that the images are magnified compared to those perceived by humans. The eyes are laterally placed (on each side of the head), prominent, and turn slightly in the orbit if necessary. This lateral position provides the horse with 180° **panoramic vision** in the vertical dimension and 140° **monocular** vision on each side (Hanggi and Ingersoll 2012). The 60° **binocular overlap** is restricted compared to humans (i.e., 120°) (Fig. 1a).

Binocular vision allows horses, like humans, to **perceive depth**. Since both eyes are spatially separated, the two images of the same object seen from different angles are combined by the brain in constructing the perception of a single 3D image (stereopsis) (Timney and Keil 1992). Horses also use binocular vision when they are especially attentive toward a neutral stimulus (e.g., Rochais et al. 2017). There are however two “blind” spots: one behind the horse, and one immediately in front (from eyes to nose) when the neck is horizontal and the head straight, but a slight head movement is enough to observe objects in these areas.

The optical axis of each eye diverges at a 40° angle from the body’s horizontal axis and is oriented toward the ground at 20° (Fig. 1b). This means that horses can see the ground 2 m ahead. Thus, grazing horses can observe grass available in front of them and what is happening in their

**Equine Sensory Systems, Fig. 1** (a) The horse’s eye and its optical axes; (b) The horse’s visual fields

### Equine Sensory Systems,

**Fig. 2** When grazing, horses must look down at their feed and be able to detect danger in the environment

surrounding environment, a clear adaptation to both feeding and awareness of potential dangers, respectively (Harman 1998) (Fig. 2). Because of this axis, they must however raise the head to observe distant objects. This means they need the freedom to move the head when directing toward an obstacle they will have to jump. Neck hyperflexion (rollkür), as seen in some dressage competitions, may prevent the horse from seeing where it is going. The pupil becomes horizontal when it retracts and the pupillary reflex to light is slow. Almost half an hour is required to adapt from full light to darkness. This explains common observations such as the reluctance of horses to enter dark corridors (or trailers).

Retinal cells transform light energy (visual stimuli) into electric impulses that are transferred to the brain (visual primary cortex) along the visual pathway. Horse retinas have a narrow band of high cell density, which seems to be responsible for visual acuity (Timney and Wright 2007). Visual acuity corresponds to the smallest perceived space between two dark points on a white background and is measured on the basis of human visual perception. Conditioning studies where horses were confronted with parallel vertical black and white stripes, that were progressively made thinner and less spaced, have allowed an estimation of horse visual acuity; horses see object details at 9 m that humans

perceive at 6 m (Timney and Keil 1992). Unless they have visual problems, horses have, therefore, a **fairly good visual acuity** (better than in most mammals; e.g., Timney and Wright 2007). It is worth noting though that out of 333 horses examined in the UK (retinoscopy), one third had visual alterations (e.g., myopia; Bracun et al. 2014). As in other mammals, two types of cells are present, i.e., rods and cones, which have pigments that absorb particular wavelengths. In horses, rods are 20 times more numerous than cones. Because rods are more than 100 times more sensitive to light than cones they are important in scotopic (crepuscular) vision. Horses also have, just behind the retina, a reflective surface (“*tapetum lucidum*”) that amplifies light, a characteristic shared with nocturnal species. Behavioral experiments have shown that they are able to **perceive** objects **in relative darkness** (under starlight in a moonless night sky) or can even move in a dark night (no star and no moon), although their acuity is then low. Rods are also involved in **movement perception**, which may explain both horse reactivity to moving objects and the ability to detect subtle movements. The famous example is Clever Hans, who was able in cognitive tests to associate involuntary cues from his owner with the expected response (see ► “Clever Hans”).

Cones, on the other hand, can only be stimulated in bright light and are responsible for color

**Equine Sensory Systems, Fig. 3** Horses are able to detect visual communication signals (a) and may recognize if another horse is attentive (b)

vision and perceiving object detail. Much contradictory information has circulated regarding color vision (or rather its absence) in horses. Anatomical studies indicate that horses, like all nonprimate mammals, have two types of cones, compared to primates that have three (Carroll et al. 2001). Since the brain constructs color perception by combining the information provided by two types of cones, this suggests that horses do indeed have color vision, but, compared to humans, of a daltonian type. Behavioral studies have proved particularly useful, although factors like luminance, or brightness, make it difficult to test “pure” colors. An early study of Grzimek (1952), using discrimination tests based on colored panels, mentioned that horses saw yellow best. Since then, different studies have been performed, involving reluctance to approach colored surfaces (Hall and Cassaday 2006). Also, discrimination testing shows that horses are able to discriminate all basic colors (red, green, yellow, blue) from gray but that they have greater difficulties where red and green are involved. There is no doubt now that **horses do have color vision**, and there seems to be a consensus now to say that horses best perceive yellow, and at least blue and green and red just as well (Blackmore et al. 2008). However, with dichromate vision, the color world of horses remains less rich than that of trichromate primates.

Visual perception has been shaped to respond to survival requirements and horses’ panoramic vision, associated with movement perception, makes them ready to react appropriately (fleeing or attack) to the approach of a hunting predator. In addition, visual acuity may help them learn about the visual characteristics of the best plants to consume.

Thanks to their visual abilities, horses have also developed the ability to detect subtle postural changes of other group members (Fig. 3) and thus avoid overt aggression (Waring 2003). This detection occurs through subtle cues in detecting changes in the attentional state of other horses (from ears and eyes positions; Fig. 3; Watham and Mc Comb 2014), or humans (they may detect gaze direction even if it is “distracted”; Sankey et al. 2011b). Even foals may observe their dam’s reactions and use them to learn about their environment (Henry et al. 2005).

## Auditory Perception

Contrarily to visual stimuli, acoustic stimuli can be perceived in variable light conditions. Sounds correspond to vibrations that travel at 340 m/s in the air. Sound frequencies correspond to the number of oscillations in cycles/sec (Hertz), and sound intensity is measured in decibels. Horse audiograms (curves based on responses in discrimination studies at different frequencies and

intensities) reveal that they perceive a **broad range of frequencies** (5 Hz–33 kHz vs. 20 Hz–17 kHz in most humans), **including ultrasounds** (Heffner and Heffner 1983). The best frequencies are very similar for horses and humans.

In all terrestrial mammals, sounds are first received by ears. The external ear includes the pinna and the auditory canal. The middle ear includes the tympanic membrane, the Eustachian tube, and the inner ear includes both the vestibule (equilibrium) and the cochlea. Ciliar cells in the cochlea transform the sound vibrations into electrical impulses that pass via the auditory nerve to the brain (primary auditory cortex).

Horses have particularly very mobile ears, with 16 different muscles that enable orientation in many directions. The direction of sound can then be detected from the front, the side, or from behind. Sudden sounds elicit the “Pryer” reflex where one or both ears turn immediately toward the sound (Fig. 4) (e.g., Basile et al. 2009). If the sound is of interest, the horse will then turn the head or even its whole body toward the general direction of the sound. Indeed, while the “horn” structure of horse ears may act as sound amplifiers and identifying sound location, horses are not very good at locating sounds. For horses to distinguish two sounds, the sounds need to be at least 25° apart (1° in humans) (Heffner and Heffner 1983).

Reactions to sounds are thus a clear representation of the importance of multimodality (involving different sensory modalities). When horses hear a sound, they will direct their visual attention toward it, probably to locate it but also to

confront both sources of information. They will show more visual attention if the sounds come from an unknown horse (Lemasson et al. 2009) or is incongruent with the visual information (Proops and McComb 2009) or situation (Sankey et al. 2011b). Here, **distant interactions will involve more bimodal (visual/auditory) perceptions.**

## Olfactory Perception

Odors are received through the nostrils to the olfactory epithelium where olfactory cells generate action potentials in response to the binding of molecules on the receptors. Olfactory information is then transmitted to the olfactory bulb and then the primary olfactory cortex. To this is added the “secondary” olfactory system, the vomeronasal organ, which is very well developed in horses where it uniquely opens in the nasal cavity. The vomeronasal epithelium also includes different types of cells. Information is then transmitted to a secondary olfactory bulb and then thalamus and amygdala. The respective functions of these two systems are poorly known. Chemical perception (olfaction and gustation) is difficult to test, as it is difficult to extract pure molecules, construct right composite odors, or to identify pertinent molecules. There is behavioral evidence that horses perceive complex odors, but the extent of their abilities remains under question. The flehmen behavior (Fig. 5a) is supposed to allow molecules to reach the vomeronasal organ better and has been thought to characterize sexual responses of stallions to sexual stimuli. Observations show that it is present in many species and that in horses both sexes may do it for detecting a diversity of odors that also include food stimuli.

Sniffing conspecifics is an important part of social encounters, sexual displays, and pre-copulatory behavior and is part of mare-foal bonding (Fig. 5b). Stallions spend time sniffing other stallions and mare feces for olfactory cues (Marinier et al. 1988). Behavioral experiments suggest that horses may discriminate sexes from urine (Hothersall et al. 2010) and determine familiarity (Péron et al. 2014). Individual recognition through odor is quite possible as horses, like the few other

**Equine Sensory Systems, Fig. 4** The “Pryer reflex”: an unusual or sudden sound induces the rotation of the ear on the corresponding side

**Equine Sensory Systems, Fig. 5** (a) A typical flehmen posture with the head and the nostrils raised, right; (b) mares spend time sniffing their newborns during the bonding process

species tested, appear to have an individual odor profile, being more similar between related individuals (siblings, parents-offspring) (Deshpande et al. 2017).

Olfaction may be associated to other modalities in multimodal representations, and **horses may associate the visual representation of a familiar human to its odor** (Lampe and Andre 2012).

A recent study has confirmed that horses, like other animals, do not have an innate recognition of predators. Odors of wolf or lion urine did not increase the heart rate of stalled horses and the odor of a wolf skin had a limited effect on vigilance. However, if blood of a stressed horse (waiting in a slaughterhouse) was associated with that of a wolf skin, vigilance increased. If then the wolf skin was associated with an unusual noise, flight reactions appeared (Christensen and Rundgren 2008). The sensory system of horses may have had some predispositions to learn a stimulus range corresponding to predator characteristics, but their functional significance requires learning. This reveals that horses are sensitive to other horses' stress odors, which may be present in a range of situations. Whether this stress level needs to be intense remains to be investigated.

Finally, odors probably play a role, together with gustation in food preferences. Horses may

eat up to different plant types per day in natural conditions and seek diversity in food ingested (Hansen 1976). Their chemical characteristics must be important. Horses do discriminate odors such as anise, coriander, and ginger (Bonde and Goodwin 1999).

## Gustation

Gustation is difficult to separate from the complementary sense of olfaction because of mixing processes involved. The back of the tongue has gustatory papilla where gustatory buds are grouped. Horses perceive the four basic flavors of sweet, salt, bitter, and sour, although with different thresholds from humans. It is probably important for horses to be able to associate flavors of food items with their postingestive consequences in order to guide food selection. Horses kept in naturalistic conditions (Fig. 6) generally avoid poisonous plants, but cases have been found of poisoning. It has been shown in horses that aversive conditioning (associative learning between a food item and postingestion sickness) requires that no more than half an hour has elapsed (Pfister et al. 2002).

Horses seem to prefer fenugreek, banana, or cherry over carrot or peppermint flavors,

**Equine Sensory Systems, Fig. 6** Horses use gustation to explore their environment

demonstrating that they clearly discriminate these flavors (Goodwin et al. 2005). Nevertheless, overall chemical perception also remains poorly known.

## Tactile Perception

The skin presents numerous receptors that transmit information about pressure, and heat/cold, contact. In horses, the skin is very thin (a few mm), but it is thicker in some areas such as the back, near the mane, and tail. Additional information is given by some hairs such as the vibrissae around the mouth, nose, and eyes (Fig. 7) which help horses detect objects or obstacles they may not have seen. The mouth mucous membrane is also highly sensitive. Horses are able to detect a fly sitting on its skin, which can be recognized by a slight movement of the skin. In a study using von Frey thin filaments (consisting of a hard plastic body extended by a

**Equine Sensory Systems, Fig. 7** Horses' vibrissae around the nose increases its tactile perception

nylon thread and calibrated to exert a specific force on the skin) applied at the base of the withers, 67% of the horses could perceive a filament of 0.02 g/m density while none of the persons tested were able to do so (Lansade et al. 2008). Tactile sensitivity is certainly largely under evaluated as riders' actions through legs and hands (conducting to the bit and thus the mouth) may be quite rough considering these thresholds.

Some parts of the body are favored for social allogrooming and their stimulation may induce a reduction of heart rate. This has induced authors to suggest that particular regions of the body relate to positive perceptions (Feh and De Mazières 1993).

Clear individual variations are evident in the reactions to tactile contact (e.g., Rochais et al. 2014). However, compared to other mammals, horses exhibit little social contact, with group proximity best predicting social affinities (Waring 2003).

## Perceptual System Asymmetry

Laterality is the systematic preference for the use of one side of the body over the other to realize motor or perceptual tasks involving paired limb or perceptual organs. In other words, laterality

manifests both on the motor (hands, feet) as well as the perceptual (eyes, ears, nostrils) level. Such behavioral laterality emerges from hemispheric lateralization, i.e., the left and right cerebral hemispheres are specialized in controlling distinct neural functions or cognitive processes. Since the late-nineteenth century, hemispheric specialization was believed to be a human specificity, but studies over the last 30 years have provided increasing evidence for lateralization in non-human mammals, including birds and even lower vertebrates (Rogers and Andrew 2002). Hemispheric specialization is assumed to confer advantage to the functioning of the brain. Among other advantages, cerebral lateralization can enhance neural capacity by allowing parallel and separate processing in the hemispheres: thus, in lateralized individuals, several cognitive tasks that demand the simultaneous but different use of both hemispheres can be performed more efficiently (Rogers and Andrew 2002). In mammals and birds, transfer of information and coordination between both cerebral hemispheres are allowed by the *corpus callosum*, the major neural pathway that connects homologous cortical areas of both sides in mammals. More recent studies in animals converge on the conclusion that stimuli, and in particular visual and auditory stimuli, with different emotional valences induce different lateralized responses. Such asymmetrical processing of emotion was largely assessed by the literature in humans leading to the establishment of two dominant theories: “the right hemisphere theory” and “the valence theory” (Davidson 1995). The right hemisphere theory defends a predominance of the right hemisphere for the processing of any stimuli expressing high emotional value. The valence theory defends rather a differential implication of the left and the right hemisphere to process stimuli depending on their emotional valence: thus, positive emotional stimuli would be preferentially processed by the left hemisphere, while the right hemisphere would be specialized for the processing of negative emotions.

Research on either motor or perceptual laterality are still scarce in equines (e.g., less than 20 scientific publications since the 2000s), but an increasing interest has been given to side bias in perceptual processing. Visual laterality

and, to a lesser extent, auditory, tactile, and olfactory have been thus demonstrated in (mostly domestic) horses.

Horses with their eyes placed laterally used them in an asymmetrical way. Due to an almost complete decussation (i.e., 80–90% vs. 50% in humans) of the optic fibers, the visual input from each eye is processed primarily by its contralateral hemisphere (e.g., Harman et al. 1999): thus, using the left (or right) eye means that the right (or left) hemisphere is used. As in other species, asymmetrical processing of visual stimuli according to emotional valence has been clearly demonstrated: when experimentally exposed to an object with a negative emotional valence (such as a veterinary shirt associated with stress-inducing situations or a novel fear-inducing object), horses use predominantly their left eye (i.e., involving the right hemisphere) rather than their right eye (i.e., involving the left hemisphere) to glance at it (Larose et al. 2006; De Boyer Des Roches et al. 2008). The tendency to look at a novel object with the left eye is even correlated to the emotional level of the horse (Larose et al. 2006): the more emotional in presence of novelty (i.e., active locomotion, increased vigilance, reluctance to approach item) the horse appears to be, the greater the proportion of time spent looking at the object with the left eye. However, novelty is not forcefully associated with a left bias in visual processing: it depends on how horses perceive the novel situation (De Boyer Des Roches et al. 2008).

Interestingly, horses can also show visual laterality in different contexts of interaction with conspecifics (with a predominant left eye use during agonistic encounters; Austin and Rogers 2012) and humans (e.g., Austin and Rogers 2007; Sankey et al. 2011a). Adult horses displayed a greater reactivity (i.e., larger flight distance) toward a “threatening” person (i.e., a person opening an umbrella and then approaching) presented in the left compared to the right monocular visual field (Austin and Rogers 2007). Similarly, 1-year-old untrained horses display asymmetrical responses to an approaching human, with more negative reactions (escapes, threats) when approached from the left side, while approaches toward the right shoulder

elicited more positive behaviors (Sankey et al. 2011a). Such visual laterality could provide important clues regarding horse perception of a particular person, or humans in general, or even work/training sessions. It is worth noting that horses trained with positive reinforcement, well known to improve horse–human relationships (e.g., Sankey et al. 2010), show no negative behavioral responses when they are approached by the left (contrary to the year-old untrained horses mentioned above). On the contrary, horses trained with more stressful approaches (such as the round-pen technique in which the horse is chased repeatedly) show a left eye preference for viewing at the trainer. Similarly, horses trained with negative reinforcement turned their heads to the right when the experimenter agitated the stick in front of them, thus looking at it with their left eye (Sankey et al. 2010).

Studies to date in other sensory modalities are scarce in equines. However, a recent study (Basile et al. 2009) revealed in the domestic horse a preponderant processing of familiar conspecific (i.e., group members and familiar neighbors) whinnies by the left hemisphere (i.e., responses with right head turning) compared to the whinnies of unfamiliar conspecifics, suggesting that the degree of familiarity influences the laterality of the auditory response. Similarly, it has been shown that the degree of novelty influences the laterality of the olfactory response, with a preponderant processing of new odors (i.e., odor of unfamiliar conspecifics) by the right hemisphere (i.e., the use of the right nostril; McGreevy and Rogers 2005).

Data in horses all converge toward a specialization of the right hemisphere for the processing of stimuli that elicit negative emotional responses, and raise questions concerning the classical practice that consists in approaching and manipulating horses on their left side.

## Individual Variations and Factors of Influence

In horses, like in any other species, individual differences exist in the reactions toward sensory stimuli. It has been proposed that sensory

sensitivity is considered a temperament trait (Lansade et al. 2008). However, if individuals do not react to a given stimulation, it may be that they do not perceive it, or that they do not react because they lack motivation or are inhibited. Thus, apathetic horses have been described in different studies on horses whose welfare was compromised or were in pain. A lowered visual and tactile reactivity was found in “depressed” horses (Fureix et al. 2012b), and stereotypic horses show opposite responses to a wither grooming to nonstereotypic horses (Normando et al. 2007). Horses may also not show reactions because of an inhibition (e.g., taught not to move). This is where behavioral observation may reach its limits and neurophysiological data are needed. Finally, developmental plasticity may influence the developmental sensory trajectory of individuals; deprived social and sensory environments during development (e.g., early individual stall housing) may well impair the development of brain sensory areas as found in other species (Hubel and Wiesel, 1963; Cousillas et al. 2004, 2006). Adult plasticity has been demonstrated in other species and would be worth investigating in equines: brain lateralization may vary with the arousal state or season in birds for example (Karino et al. 2016). Promising approaches, such as electrophysiological recordings of brain activity in free-moving horses, will help fill the gap between anatomy and behavior (Cousillas et al. 2017).

## Erasmus Darwin

Michael Stock

MacEwan University, Edmonton, AB, Canada

The grandfather of both Charles Darwin and Francis Galton, Erasmus Darwin was born in Elston, UK, on December 12, 1731. Trained as a physician at the University of Edinburgh, Darwin had a successful medical practice based in Lichfield, in the midlands of England. By some accounts, he was the finest physician in England at the time (King-Hele 1977). He declined the opportunity to move to London as royal physician to treat King George III for his bouts of mental illness. A compassionate man of unending curiosity, he was an enthusiastic amateur natural philosopher. After forming the Botanical Society of Lichfield, he translated the works of Linnaeus from Latin to English and published the taxonomic work as “*A System of Vegetables*” and “*The Family of Plants*” from 1783 to 1787 (Darwin 1782–1783; Darwin 1791). Because Linnaeus had classified plants based on the structure of their flowers, Darwin converted this into a long poem, “*The Loves of the Plants*” which was shocking for the times, because it was so sexually explicit. For example, grapevine (*Vitis*) is described as “Seductive harlot” because the flowers have 5 stamens (male parts) and 1 pistil (female); Rose campion (*Lychnis*), with 10 stamens and 5 pistils as “Wanton beauties in gay undress” (Browne 1989). In this way, Darwin popularized science. *The Botanic Garden* sold well, was translated for European audiences, and Darwin became well-known as a writer and poet.

Erasmus was a founding member of the Lunar Society (which met near full moons), a group of politically progressive scientists, industrialists, and inventors that included among others the potter Josiah Wedgwood; developer of the steam engine, James Watt; and the chemist Joseph Priestly. Darwin was also a friend of Benjamin Franklin. The society was anti-slavery, promoted the Industrial Revolution and supported the French and American Revolutions (positions which would later get some members in trouble with society and the law). Darwin also belonged to the Derby Philosophical Society, which promoted experiments with gases to treat diseases such as cancer and infections. The author of *Frankenstein*, Mary Shelly, attributed some of Darwin's experiments as inspiration for her novel (Shelley 1818).

Although he did not patent his ideas, Darwin invented a horizontal windmill (used at Wedgwood's pottery to grind pigment) and after being injured in a carriage accident that damaged his knee, invented a stabilizing system to prevent carriages from tipping and a steering mechanism that was later used in automobiles. He also envisioned a speaking machine, a canal lift, a copying machine, a rocket engine, weather monitors (which were used for many years), and even a mechanical bird. While convalescing from his accident, Darwin began to consider theories about the relationship between mind and body, about medical practice and theory, and even about the origin of the Earth and the history of life. These ideas led to the publication of his most controversial and famous work, *Zoonomia: The Laws of Organic Life* (1794–1796) (Darwin 1796).

*Zoonomia* was a massive work (586 pages). In it, Darwin covered his theory of disease and classified various illnesses in charts. The book was used as a medical text. Darwin was influenced by the medical doctor and philosopher David Hartley (1705–1757), who suggested that vibrations detected by the five senses became ideas. This was a materialistic (some argued atheistic) view that linked humans with animals. Darwin suggested that the human body was composed of fibers and nerves, and that “motions” were detected by the senses, translated into ideas in the brain, and that patterns of experience could

be passed down generations (associationism). The most controversial ideas were presented in a chapter called *Generation*.

In *Generation*, Darwin suggested that the earth was ancient and that life formed from minute filaments in prehistoric seas. From this early form of life, Darwin suggested that the environment had caused organisms to evolve adaptations to satisfy their “*perpetual endeavor to supply the want of food*.” Erasmus Darwin's driving force for evolution (change through time) was not natural selection but an innate drive caused by needs to meet environmental challenges. He thought that fossils provided evidence of descent and that humans were animals and a part of the vast array of life. He made no attempt to reconcile his views with standard biblical interpretations. Darwin also went on in a book published after his death, “*The Origin of Society*” to reiterate his ideas for the origin and history of life and suggested that human societies evolved from monarchies to democratic/republican systems (Darwin 1803).

After publication, *Zoonomia* was greeted with severe criticism (Garfinkle 1955). It was considered subversive, a horror, a monstrosity, atheistic and that it degraded humans and exalted animals. One reviewer despised Darwin's “*total denial of any interference of a Deity in the creation and preservation of everything that exists*” (Hardin 1959). The ideas expressed by Erasmus Darwin were considered to menace the social order in England. The publisher of *Zoonomia*, Joseph Johnson was imprisoned. Because of the heretical nature of *Zoonomia*, it was placed on the papal index of prohibited books in 1817. A long parody poem of *The Loves of the Plants*, called “*The Loves of the Triangles*” led to widespread ridicule of Darwin and his eccentric ideas (Fara 2012).

Nevertheless, many of the ideas in *Zoonomia* resonated. In France, Jean Baptiste de Lamarck adopted the same idea that organisms responded to the environment by changing over time from generation to generation (evolution) due to needs (*besoins*) and that these had created new species (*Philosophie Zoologique* 1809). Lamarck, however, was not aware of Darwin's work (Mayr 1982).

Because of the ridicule directed at Erasmus Darwin, the term “*Darwinism*” became a derogatory expression for fanciful speculation, which was later applied to his grandson’s work. Charles Darwin read *Zoonomia* twice and concepts such as the old age of the Earth, vestigial organs (“wounds of evolution”), sexual selection, analogies and homologies, hereditary diseases, and inbreeding, among others, which appear in *Origin of the Species*, occurred in germinal form in *Zoonomia* (Darwin 1859). Charles did refute the idea that his grandfather’s writing directly influenced his work on natural selection and

decried the fact that *Zoonomia* offered little concrete evidence to back up the theories it presented (Stott 2012). It is likely that one of the reasons that Charles Darwin took so long to publish *Origin of Species*, and assembled so much supporting evidence for natural selection, was because of the scorn that his grandfather had incurred (Hardin 1959).

Although there were some similarities and many differences between grandson and grandfather (see Table 1), Erasmus Darwin deserves to be better known for his historical role as a progressive free-thinker who was not afraid to challenge established

**Erasmus Darwin, Table 1** Erasmus Darwin compared with grandson, Charles Darwin

The main agent of change was natural selection due to the non-random survival of randomly generated varieties. Evolution was not goal directed                                        |

ideas (King-Hele 1999, 2003, 2007). He used his great observational skills (honed to diagnose and treat patients) to observe the natural world. He linked the practice of medicine to broader ideas about the substance of life, where and how life arose, and its history. He tried to explain how sensations could mechanistically be transformed to ideas. He was a social activist who provided medical care to the poor for free, promoted education for women, and opposed slavery. Samuel Taylor Coleridge is said to have stated that Erasmus Darwin had a "... greater range of knowledge than any other man in Europe" at the time (Barber 1980; Chancellor 1976). William Goodwin in 1797 claimed Darwin as "so extraordinary a man" in his list of "lions" of the day (Hardin 1959). However, Erasmus Darwin has been accused of not being original – that he merely synthesized and popularized the ideas of others (Mayr 1982), an accusation his grandson would also face. Erasmus Darwin died of a heart attack at Breadsall, UK, on April 18, 1802 (King-Hele 1977).

## Error Rate

Benjamin R. Eisenreich  
University of Rochester, Rochester, NY, USA

## Definition

Error rate may refer to a variety of methodological and statistical procedures used within experimental studies. With respect to the former, error rate is typically characterized as a performance criterion used for assessing a variable of interest, for example, learning. In regards to statistics, error rate refers to the significance level, alpha, utilized in null hypothesis testing.

## Introduction

At a basic level, error rates can be understood as occurring within the signal detection schematic outlined in Fig. 1. If we consider a simple task in

|                                        | Flashing light is present | Flashing light is absent |
|----------------------------------------|---------------------------|--------------------------|
| Response: “There is a flashing light”  | Correct detection         | False-Positive           |
| Response: “There is no flashing light” | False-Negative            | Correct rejection        |

**Error Rate, Fig. 1** Schematic of signal detection theory for a light discrimination task

which a subject must indicate the absence or presence of a flashing light, two types of errors can occur, false negatives and false positives. False negatives occur when the subject identifies the light as being absent when in fact the light was actually there, while false positives occur when the subject indicates the presence of the flashing light in its absence. Combined together, these two measures can provide insight into sensory processes related to detection and discrimination, as well as other cognitive processes.

**Error Rate as a Performance Criterion**

As a performance measure, error rate refers to behavior that deviates from a stated criterion. Consider a prototypical experiment in which a rat is trained to turn left within a T- maze in order to obtain a sugar pellet. Within this setup there is a performance criterion identified as “turning left” in the maze. Alternatively, “turning right” within this setup is conceptualized as committing an error. By analyzing the behavior of the rat placed within the maze over multiple time points to the criterion of “turning left,” an overall rate of errors committed or error rate can be determined.

Typical studies of animal behavior and cognition utilize the above defined error rate as a means of analyzing how animals learn and perceive their environment. For example in reinforcement learning, the error rate functions as an index of the associative strength between a stimulus and particular response contingency (Sutton and Barto 1998). As the animal learns the association between a stimulus and a specified response–reward contingency, they become

more likely to engage in the specified response. Within this setup, as the error rate decreases, the animal can be said to have learned the relationship between the stimulus and reinforcement contingency.

Error rates can also provide insight into the cognitive capacities of animals. Within reversal tasks where the pairing between stimuli A1 A2 with rewards R1 R2 is reversed after stable performance (i.e., A2 now signals R1 and A1 now signals R2), the error rate or amount of responding on the now unrewarded stimulus provides insight into the cognitive flexibility of the organism in recognizing and adapting to changing environmental contingencies (Bond et al. 2007) as well as the underlying neural circuits (Guise and Shapiro 2017). Likewise, cognitive capacities related to working memory and metacognition are often assessed by examining error rates for false negatives and positives in memory recall tasks and investigations of metacognition (Smith 2009).

**Error Rate Within Null Hypothesis Testing**

Within null hypothesis testing, error rates refer to two main types of conclusions regarding the plausibility of the null hypothesis a researcher may arrive at, termed type I and type II errors. A type I error is characterized by an incorrect rejection of the null hypothesis and is related to the significance level of the test or alpha ( $\alpha$ ) value. In simple terms, a type I error occurs when a particular relationship between the dependent and independent variable is reported, when in fact no

relationship exists (this corresponds to a false positive in Fig. 1). Conversely, a type II error is characterized by an incorrect failure to reject the null hypothesis, akin to failing to detect a relationship between the independent and dependent variables (this corresponds with a false negative in Fig. 1). As with type I errors, type II errors are related to statistical power and are defined as beta ( $\beta$ ).

As a general convention, the type I error rate specified by alpha is typically set at or below .05. This value represents the likelihood of observing the data given the null hypothesis is true. One consideration when conducting multiple statistical tests is the compounding of type I errors that arises when examining each additional hypothesis, known as the family-wise error rate. In order to avoid this potential pitfall, it is wise to adjust the alpha level using a statistical procedure, such as the Bonferroni correction (Kirk 2008).

## Escape Behavior

► [Escape Response](#)

## Escape Motion

► [Escape Response](#)

## Escape Response

Emily Patterson-Kane

Animal Welfare Division, American Veterinary Medical Association (AVMA), Schaumburg, IL, USA

## Synonyms

[Escape behavior](#); [Escape motion](#)

## Definition

An escape response is a coordinated response by an animal to end exposure to a noxious stimulus or potentially dangerous experience. Escape responses may be innate or learned and function to improve the survival of the animal.

## Introduction

An escape response functions to terminate a negative experience or exposure to a hazard. It will take a form likely to produce this outcome, which may be fleeing, hiding, or releasing materials. For example, a marine mollusk such as an octopus may release ink (Derby 2007), or an insect such as an aphid may drop from a branch (Gish and Inbar 2006). Many animals will flee rapidly from a threat along an unpredictable trajectory or zig-zag path. Predator escape is one of the most commonly studied escape responses; however, it may be shown in response to a range of stimuli such as temperature extremes, a source of pain, or any sudden intense stimulus.

Escape responses with a known and predictable form may have a specific name. For example, the “C-start” is a sudden turn and acceleration shown by fish avoiding a predator (Eaton and Emberley 1991) and is named after how the fish’s body appears from above as it makes its sudden turn. Crustaceans such as shrimp rapidly escape predators with a tail-flipping motion called

the caridoid escape reaction (Faulkes 2015; Heitler et al. 2000).

As some escape responses can be reliably elicited, they are convenient models for assessing how the nervous system evolved, how the behavior is elicited and performed, and how environmental variables and various types of learning modify the response. For example, the tail-flipping escape response circuit of crustaceans such as shrimp, which is relatively simple and mediated by giant interneurons, appears to be ancestral to all decapods (Faulkes 2015).

### **As Distinct from Avoidance**

If a behavior allows an animal to prevent its exposure to a stimulus that would otherwise elicit an escape response, this constitutes an avoidance response. However, the distinction between escape and avoidance is less clear when considering the role of the stress or anxiety felt in anticipation of a predictable or signaled danger. That is, a behavior that prevents the animal from encountering a hazard may be maintained through escape behavior that occurs as soon as the animal experiences a conditioned fear response provoked by stimuli that indicate the hazard may be nearby. These conditioned fears are seen as animals acquire fear of predators but then also of conditions where predators hunt more effectively such as open or brightly lit areas (Griffin et al. 2000).

### **Absence of Escape Behavior and Learned Helplessness**

When animals find they are unable to escape a noxious stimulus, they may stop performing escape behavior, and this passivity may persist into situations where an escape response would be effective. This failure to perform an available escape response due to prior learning is referred to as “learned helplessness” (Maier and Seligman 1976). This conditioned absence of an escape

response is associated with chronic negative welfare states such as depression (Maier 1984).

### **Marginal Cases**

The status of some behaviors as escape responses is speculative or disputed. For example, some researchers suggest that self-mutilation behavior may function to end stressful demands or unpleasant internal states or to cope with unstimulating environments (Carr 1977). And bar-chewing by rats and mice, once considered a stereotypy, is now widely considered to be an escape-motivated behavior (Lewis and Hurst 2004). Where the response is not rapid and clearly elicited by an observable stimulus, or is not effective in the animal’s current environment, its role as an escape response may be more difficult to establish.

### **Modifications**

Escape responses are modified by many variables. For example, animals in groups may show an escape behavior without ever experiencing the eliciting stimulus if they imitate the escape responses of conspecifics (Herbert-Read et al. 2015). And there is evidence that animals show reduced or absent escape responses to predators when influenced by parasites that rely on predation to complete their life cycle (Holland and Cox 2001; Libersat and Moore 2000).

### **Conclusion**

Escape responses are a class of behaviors that remove an animal from an aversive or dangerous situation. Due to the high survival value of this behavior, it can often be reliably produced and systematically studied. For this reason, the study of escape behaviors has contributed to knowledge of the neural and psychological basis for behavior in many different species.

## Essentialism

Hannes Rakoczy<sup>1</sup> and Trix Cacchione<sup>2</sup>

<sup>1</sup>University of Göttingen, Göttingen, Germany

<sup>2</sup>Fachhochschule Nordwestschweiz, Brugg, Switzerland

## What Is Psychological Essentialism?

Much of human cognition is characterized by psychological essentialism (Gelman 2003). In its broadest form, psychological essentialism is a conceptual framework that defines our naïve-metaphysical perspective on the structure of objects and categories. Its basis is the distinction between two kinds of properties: Objects of a given kind can have many *accidental* properties: These are properties that the object in question can but need not have, and in respect to which it can change without becoming a different kind of object. *Essential* properties (Essential properties are sometimes called “defining,” and accidental ones “characteristic.” Research in cognitive development, for example, suggests that children’s lexical semantics undergo a “characteristic-to-defining” shift in the preschool years such that children initially base word meaning on superficial features associated with prototypical instances of a given kind, and only later focus on the defining features underlying the category and its prototypical as well as less prototypical members alike (Keil and Battermann 1984)), in contrast, are those properties that make an object the kind of object it is and that thus define its very identity.

Whether something is a piece of gold is a question of its deep, essential (chemical) properties. If you change these properties, the object in question is no longer a piece of gold. Pieces of gold, on the other hand, usually have some prototypical surface features like looking golden. But these are merely accidental, not defining or essential, features. You can change them, for example, by painting the piece green, without altering the very identity of the object.

Importantly, psychological essentialism is a rather general and abstract framework and we often do not need to know what exactly the essential properties in question are in order to assume that there are some. This is particularly clear in the case of many of our natural kind concepts. No layperson has any idea about the essential properties of being a tiger, elm, or piece of gold (Kripke 1972; Putnam 1975). We are often able to refer to and pick out objects of these kinds demonstratively (“This is a tiger”), and we assume that there must be a deep, underlying essence (its tiger-ness) that defines its natural kind, but mostly we either defer to authority (“zoologists know”) or future research (“they’ll find out”) when having to explain what this essence may be. Our concepts of “tiger”, “elm,” and “gold” function, as it were, as *essence placeholders* (Medin and Ortony 1989).

### The Scope of Psychological Essentialism

The most obvious domain of application of psychological essentialism is thought about natural kinds, and in particular biological kinds. Typically, adult humans share the intuition that biological natural kinds, such as tigers and elms, are constituted by shared, deep essential properties that are largely unknown to the folk, but may be specified by scientists or other experts (Atran 1998). Some form of psychological essentialism, however, seems also to be at work in our categorization of artifacts – whose essences have to do with history of invention, production, and use (Bloom 1996; Gelman 2013). Another prominent area in which psychological essentialism features prominently is social categorization: For many social categories, for example, gender, ethnicity, race, or social class, adult humans tend to posit deep, underlying essential properties (even if they are unknown) that contrast with merely superficial accidental properties (Rhodes and Mandalaywala 2017).

### Signatures of Psychological Essentialism

From a logical point of view, at the heart of psychological essentialism lies the distinction

between deep essential and superficial accidental properties. Typically, in human adults this distinction has a characteristic signature or pattern of manifestations:

- Categories to which psychological essentialism applies are seen as natural kinds that – unlike merely nominal kinds (such as Tuesdays) – are real and objective and out there in the world even if we (still) do not know what their essence is.
- Though considered as radically different, essential and accidental properties are seen as causally related in characteristic ways: Members of a given kind have many of their accidental properties in virtue of their hidden essence that somehow produces patterns of perceivable characteristic features (tigers look like tigers because of their tiger-hood).
- At a given time, membership in such categories (and thus the identity of a given object as object of this kind) is a binary rather than fuzzy matter.
- Over time, membership in the category remains stable even over major transformations of accidental properties (as long as these changes do not affect the essential properties).
- Within the category, there is a tendency to see its members as more homogenous than they really are (like in categorical perception, where analogous stimulus differences are underestimated within and overestimated between categories).

### Virtues and Vices of Psychological Essentialism

From a pragmatic point of view, psychological essentialism has many virtues: It is, above all, a powerful cognitive framework for inductive learning and the development of naïve theories. It has been argued, however, that it also comes with cognitive and moral detriments. Cognitively, a rigid overapplication of essentialist assumptions of the stability and unchangeability of natural kinds stands in the way of understanding the dynamic picture of species and their evolution

according to Darwinian theory, for example (Gelman and Rhodes 2012; Mayr 1982). Morally, psychological essentialism with regard to social kind can tend to foster racism, sexism, and other evils (Haslam and Whelan 2008).

### **Empirical Indicators of Psychological Essentialism in Human Adults and Older Children**

The signatures of psychological essentialism mentioned above can be tapped empirically in various ways. Studies on category-based induction, for example, have widely documented that subjects make inductive inferences from some sample objects to other objects based on essential properties rather than their surface accidental properties (Gelman and Davidson 2013). Most prominent, and most relevant for the evolutionary and ontogenetic question in focus here, have been studies that address subjects' intuition of identity and stability of kind membership over time and over various dramatic property changes (Keil 1989). In one kind of vignette, for example, animals of a given kind (say, piglets) are adopted and raised by animals of another kind (say, tigers) and learn to behave like them, etc. In another kind of vignette, an animal of a given kind (e.g., racoon) is superficially transformed by being shaved, painted or even by surgical treatments to look (and even smell) like an animal of a different kind (e.g., skunk). In both cases, the target question is what the original animal will end up and turn out to be (Keil 1989). In both cases, human adults and children from age 4 to 5 are very firm in their intuition: You can adopt or superficially transform animals as much as you want to, but this will never turn them into animals of a different kind.

### **Roots of Psychological Essentialism**

While psychological essentialism has been amply documented in adult humans and older children, little is known so far about its origins, both ontogenetically and phylogenetically. This is partly

due to methodological reasons: Most studies on psychological essentialism heavily rely on language as dependent measure (participants are asked to make explicit identity and category judgments such as “Will this animal end up as a racoon or a skunk?”), and are therefore not suitable for testing nonverbal animals or preverbal infants. This may, however, also partly be due to theoretical reasons. It has been argued that psychological essentialism is a “late and sophisticated achievement” (Fodor 1998, p. 159), both historically and ontogenetically, that heavily rests on linguistic and technological foundations. According to this argument, it simply would not make sense to even look for basic forms of psychological essentialism in infants or nonhuman primates.

### **Sortal Object Individuation**

However, recent research in developmental and comparative psychology has begun to use alternative, nonverbal methods in order to explore ontogenetic and phylogenetic roots of psychological essentialism. This research is based on the assumption that psychological essentialism need not come as an all or nothing package. Rather, it may develop in steps, and there may be more basic and foundational forms of essentialism in which not all of the characteristic adult signatures (see above) are present yet. Quite plausibly, the most basic form of essentialism builds on basic object cognition, namely on intuitions about the identity and stability of objects as members of a given kind – without necessarily including other signatures such as understanding the causal relatedness of essential and accidental object properties. And quite plausibly, the primordial form of such intuitions is found in sortal object individuation (Xu and Carey 1996).

Sortal concepts are kind concepts, linguistically typically reflected in the form of count nouns, such as “tiger,” “car,” or “duck.” Sortal concepts supply criteria of individuation and countability (whenever one can reasonably ask “How many Xs are in the room?” “X” is a sortal concept), and identity (such that one can ask and answer questions of the form “Is this the same X as the one that was here a while ago?”). Sortal object individuation is the capacity to use such

sortal concepts to individuate, identify, and track objects. The crucial point for present purposes is the following: Given their role in identity judgments, sortal concepts already involve a basic distinction between essential properties that do preserve identity (even if they are unknown) and merely accidental properties that are irrelevant to identity questions.

Sortal object individuation has been studied in human infants, since a pioneering study by Xu and Carey (1996), with designs like the following: The infant is confronted with a box into which an object of kind A enters at time 1, followed by an object of kind B that comes out of the box at time 2. The central dependent variable is subjects' numerical expectation as to how many objects are in the box, as indexed by their looking and searching behavior. If they individuate the objects as objects of distinct kinds that cannot turn into each other, they should expect that there must be still (at least) one object, the object of kind A, in the box. Basic versions of such tasks in which an object of kind A (e.g., a ball) and an object of kind B (e.g., a toy duck) are used that differ both in essential and superficial properties are mastered by human infants from around 12 months (Xu 2007). Interestingly, this is the age at which children begin to acquire serious language competence and, indeed, some studies found that sortal object individuation and language development go hand in hand: The children who solve a given sortal individuation task tend to be those children who already understand the requisite words ("ball," "duck"), and children generally perform better when the objects are explicitly labeled (Xu 2002). This has led to speculations, in line with a long philosophical tradition (e.g., Quine 1957), that sortal object individuation may be basically a linguistically grounded phenomenon (Xu 2002).

However, subsequent comparative studies with analogous tasks amply documented the very same capacities in nonhuman primates (Mendes et al. 2008, 2011; Phillips and Santos 2007; Phillips et al. 2010; Santos et al. 2002). And some studies with dogs and birds even suggest that sortal object individuation may be more ancient and widespread beyond the primate lineage (Bräuer and

Call 2011; Fontanari et al. 2011, 2014). Therefore, on the premise that these kinds of tasks really tap sortal object individuation, this capacity seems to be older than language and clearly not uniquely human.

But is this premise justified? Does one really need to use sortal concepts in order to solve these tasks? The basic methodological problem is that in these scenarios, information about the kinds of objects (their essential properties) and information about their merely superficial properties are necessarily confounded (balls and toys ducks are different kinds of objects, but they also look very different). And so success in these tasks could be more parsimoniously explained on the basis of tracking superficial (rather than essential) properties.

Another set of studies, therefore, combined the logic of such individuation studies with the logic of verbal transformation stories (used in research on psychological essentialism) in order to investigate whether infants and nonhuman primates really make use of sortal (and not just property-based) object individuation. In one study, 14-month-old infants saw events of the following structure: at time 1, an object with appearance A (e.g., a toy bunny) entered into a box, and at time 2 infants either saw an object with appearance A (same bunny) or with appearance B (e.g., toy carrot) come out of the box (Cacchione et al. 2013). The two appearances, in real fact, belonged to one and the same object (a soft toy that could be turned inside out, with carrot-appearances on one side, and bunny-appearances on the other). Crucially, there were two groups of infants: One had been previously familiarized with such dual-aspect objects, while the other one had not. The ignorant infants took the difference in superficial appearance as diagnostic for questions of numerical identity (they searched longer in the bunny/rabbit condition than in the bunny/bunny condition). The infants in the other group (familiar with such dual-identity objects), in contrast, ignored the superficial differences for their judgment of numerical identity (they did not search differently in the two conditions). That is, given the requisite background knowledge, infants disregard the superficial feature differences in much the same

way as older children disregard the superficial feature differences between a normal racoon at time 1 and a skunk-looking racoon at time 2 (after it has been painted, etc.), when it comes to the question of the animal's identity.

In another study with a slightly different approach, great apes saw a food item of kind A (e.g., slice of banana) enter into a box and a food item either of kind A or of kind B (e.g., slice of carrot) come out of the box. Crucially, in some conditions, the food item entering the box was first changed in its superficial properties (e.g., the banana slice was painted orange) so that it was perceptually more similar to items of kind B than to other items of kind A. The findings were very clear: Apes treated kind information as more valuable than surface feature information when inferring the number of objects present in the box. They searched longer in conditions involving a difference in kind between the object placed and the object retrieved from the box (as compared to conditions involving only surface feature differences) (Cacchione et al. 2016).

### **Distinguishing Deep/Inside from Superficial/Outside Features**

Converging evidence for a systematic distinction between deep and superficial features in 14-month-old human infants comes from a study by Newman and colleagues (Newman et al. 2008): When trying to figure out the sources of behavior of a self-propelled object (e.g., a toy cat), infants searched more for its internal (deep) rather than its external (superficial) features. That is, they seem to appreciate that the self-generated movement of agents is more likely to be caused by deep internal properties than by more accidental external features.

### **Summary and Outlook**

Psychological essentialism marks a fundamental way of human thinking about the natural and the social world. The workings of psychological essentialism and its underpinnings have been extensively studied in research in cognitive and social psychology. From an evolutionary and

ontogenetic point of view, however, still little is known about its origins and roots. It has sometimes been assumed that essentialism crucially builds on sophisticated linguistic and cultural influences, and should thus emerge relatively late both phylo- and ontogenetically. Recent comparative and developmental research, in contrast, highlights the possibility that precursors and/or basic forms of essentialist thought develop early in humans and are shared with other species in the primate lineage and possibly beyond. In particular, sortal object individuation – the capacity to keep track of a given object as object of a certain kind over time – may be a primordial form of essentialist cognition. It may be the first clear form of fundamental distinguishing between essential properties of objects that determine their identity over time and merely accidental properties that can be changed without altering the object's identity.

Many open questions remain for future research, of course: Is sortal object individuation merely a precursor to or rather already an early form of psychological essentialism? Resolving this question may be largely a terminological matter: If psychological essentialism is conceived in such a way that its core is the distinction between essential and accidental properties and that it can otherwise come in degrees, sortal object individuation appears as one (perhaps even the) basic form of essentialist cognition. If, however, psychological essentialism is seen itself as an all-or-nothing matter that necessarily involves all the different signatures found in adults, then sortal object individuation may be merely a precursor.

What is currently largely unknown is how other signatures typically associated with psychological essentialism (such as assumptions about the causal relations between essential and accidental properties) develop(ed) through ontogeny and evolution. Relatedly, how do children develop the barebones of essentialist sortal object individuation into the full-fledged adult framework of essentialist reasoning? Finally, what other potential foundations of essentialist cognition may there be, and how do they relate to sortal object individuation? It has been suggested, for example, that human essentialism develops out of

a fundamental cognitive tendency to explain events and patterns by focusing on inherent features of the relevant constituents, the so-called inherence heuristics (Cimpian and Salomon 2014). Future research will need to clarify whether such a heuristic is an additional and complementary building block out of which full-fledged psychological essentialism finally develops; or alternatively, whether it is even the most basic cognitive foundation that underlies psychological essentialism.

## Introduction

Over the past 30 years, evidence has revealed that estrogen effects on behavior transcend that of sexual behavior and in fact have profound effects on cognitive function in animals and humans. This entry briefly summarizes the effects of estrogen on the central nervous system, including structural and local synthetic effects, and how these actions modify cognitive differences between sexes, menstrual phases, and the

menopausal transition. Finally, this entry will explore implications for estrogen therapy as it relates to cognitive dysfunction and aging.

## Mechanisms of Estrogen Action on the Central Nervous System

Estrogen is a steroid hormone best known for sexual differentiation and reproduction. Estrogenic modulation of brain regions and cognitive function first begins in utero, continues through adolescence, and reaches its highest impact in adulthood when regular hormone secretions reach their highest levels before rapidly plummeting with aging. Estrogen-dependent effects on cognition have largely been attributed to both classic, genomic mechanisms – hormone binding to nuclear receptors and modification of gene transcription. The receptors mainly responsible for such ligand-activated transcription are estrogen receptor ER- $\alpha$  and ER- $\beta$ . Both are distributed throughout the body, including several areas of the central nervous system that coordinate cognitive function, including the cortex, amygdala, hippocampus, basal forebrain, cerebellum, locus coeruleus, raphe, and central gray matter. The ER subtypes differ in localization, binding affinities for ligands and modulators, and effects on cognition (Luine 2014).

Subcellular localization of ERs to the plasma membrane of neurites, soma, dendritic spines, and axon neurons suggests another role for estrogens as a mediator of synaptic transmission (McEwen and Alves 1999). Estradiol can also bind to a G-protein coupled receptor (GPR30) which is expressed in the hippocampus. The role of this receptor remains unclear, but it is thought to promote cell signaling (Brailoiu et al. 2007). Finally, there is evidence for in situ production of estradiol, likely resulting from conversion of other steroids (i.e., testosterone or cholesterol), by aromatase in discrete brain regions. Local accumulation may represent a neuromodulatory role for estrogen as neurosteroid, potentially mediating synaptic connectivity (Balthazart and Ball 2006). In summary, estrogen effects on the brain are complex and regulated through an array of

cellular mechanisms that likely work in concert to influence cognition.

## Estrogen and Cognition

The role of estrogen in sex-specific events (menstruation, pregnancy, and menopause) is outside the scope of this review. To summarize briefly, gonadal production of testosterone begins in utero and directly masculinizes the male genitalia. In the central nervous system, testosterone is aromatized to estradiol and together these hormones program sexual behavior. In many animal species, sexual behaviors are strikingly different. Males exhibit mounting, while females exhibit lordosis. What is less apparent is that there are also sex-differences in nonsexual behaviors. For example, male rodents immediately outperform females on tasks requiring spatial memory, while females tend to take longer to acquire visual representation of spatial cues, but once they do they retain task performance even after environmental alterations (Luine 2014; Williams et al. 1990).

Similar sex differences in cognition are evident in human studies. As with rodents, men tend to outperform women in tasks require spatial cues. Women, however, are superior to men in aspects of verbal abilities, including spelling, grammar, and speech acquisition. Women also tend to outperform men in tests of perceptual speed and accuracy and exhibit better short-term memory. Overall sex differences in cognitive function in rodents and humans is small in magnitude, but it is important to note that differences in spatial abilities are present in children and become larger at puberty suggesting that differences are driven by both organizational and activational hormone effects (Luine 2014).

Further demonstrating activational effects of estrogen are differences in cognitive performance throughout the estrous and menstrual cycles. Physiological fluctuations in ovarian hormones across cycles allow for noninvasive studies of the effects of estrogen on cognition. During proestrus, when estrogen peaks in rodents, females

demonstrate better recognition and spatial memory compared to those in different phases of the estrous cycle (Frick and Berger-Sweeney 2001; Frye et al. 2007; Walf et al. 2006). One reason for this may be estrogen effects on the stress-experience. The majority of rodent learning and memory tests introduce stress via negative (shock) and positive (food deprivation prior to reinforcement) reinforcement, as well as extensive handling. Estradiol administered to ovariectomized rats has been shown to decrease anxiety and depression in laboratory tests, making it difficult to determine cycle-related changes to cognition independent of stress effects (Frye et al. 2007). Nevertheless, human studies have reported menstrual cycle effects on tasks specific to spatial and working memory. However, the results are inconsistent and seem to be specific to spatial tasks (Luine 2014).

The majority of evidence for a role for estrogen on cognitive function comes from ovariectomized rodent studies. Ovariectomized rats show impaired performance on tasks requiring spatial working memory that can be improved by estradiol treatment. Other evidence suggests that estrogen replacement specifically enhances acquisition, but not reference memory. Such activity may be explained by estrogen enhancement of cholinergic function and increasing dendritic spine density. In monkeys, ovariectomy reduces, while estrogen and progesterone replacement restores the density of axons related to acetylcholine and dopamine neurotransmission in the prefrontal cortex (Kritzer and Kohama 1998). In humans, this region plays an important role in information processing, thus decreased estrogen levels may play critical role in age-related declines in cognitive function, especially short-term memory, seen in postmenopausal women.

## Estrogen and Cognitive Loss

One of the most important areas of study in the estrogen and cognition field is age-related cognitive decline. While it is difficult to ascribe a

specific role for estrogen in the neurogenerative due to other factors associated with the aging process, the potential impact of the hypo-estrogenic state following menopause is an important area of study. There is a clear sex-difference in the development and pattern of neurodegenerative disease. For example, females are more likely to develop Alzheimer's disease than males although the mechanism is unknown. Studies in rodents propose that decreased spine density in the prefrontal cortex and hippocampus are decreased following ovariectomy, but less significantly so with normal aging (Luine 2014). Structural changes along with impaired spatial memory in these animals suggest synaptic reorganization resulting from low estrogen levels.

Whether connectivity and working memory can be restored by estrogen treatment is a critical unanswered question. During the 1980s and 1990s estrogen therapy was demonstrated to promote memory during aging in several observational studies. However, longer trials using hormone replacement therapy in women suffering from Alzheimer's disease found no cognitive benefit (Luine 2014). Several expert sources have tried to pin the critical period hypothesis as a reason for inconsistencies in the literature on estrogen therapy and neuroprotection. According to the critical period, estrogen therapy will only have an effect on aspects of cognition if it is initiated soon after menopause. It has been suggested that exogenous estrogen effects are impaired by already existing adverse modifications such as reduction in brain volume, synaptic connectivity, and neurotransmitter systems; thus delayed neuroprotective effects are putative. There is some evidence for this theory in rodents (reviewed in Daniel 2013). For example, rats given estrogen replacements immediately after ovariectomy at middle age demonstrated superior learning in old age compared to animals ovariectomized at the same age but receiving no therapy. These rats, which were given estrogen for a short period also showed similar learning and memory as ovariectomized rats that received continuous replacement therapy thus indicating

the need for studying the regimen of replacement therapy.

Finally, premenopausal women experience cyclic fluctuations in estradiol, as specific hormone, 17 $\beta$ -estradiol. These fluctuations co-occur with fluctuations in another hormone, progesterone. Therefore, there is still work to be done to determine how specific hormonal interactions and delivery may affect normal and pathological changes in cognition (Luine 2014). Currently, the main confounder in existing studies is the use of conjugated equine estrogen (CEE) as hormone therapy. CEE is a mixture of conjugated estrogens, including sodium estrone sulfate and sodium equilin sulfate, among others, and only trace amounts of estradiol. For this reason, it is difficult to correlate the results of hormone replacement therapy using CEE to estradiol replacement. Interestingly, since its approval in 1942, the marketed version of CEE – Premarin, has been the only available compound for hormone replacement therapy. While new routes of administration have been developed, no novel estradiol-based compounds have been brought to the market. In the past two decades, selective estrogen receptor modulators (SERMS) have been developed for the treatment of other estrogen related conditions, such as osteoporosis and breast cancer (Luine 2014). The ability of SERMS to directly target specific estrogen receptors represents an exciting new avenue to research the role of estrogen on cognition and potential therapeutic targets.

## Conclusions

Awareness of estrogen effects on cognition has grown immensely over the past several decades (Luine 2014); however, the neural action of estrogen is still not well understood. Estrogen receptors are now known to be nuclear, localized to the plasma membrane, and function via G-protein coupled signaling pathways. Local synthesis of estrogen is another potential way by which estrogen may function as a neuroprotectant. There is

still much to uncover regarding the neural mechanisms for estrogen action, including the effects of specific isomers, timing, and delivery. Future research is necessary for understanding estrogen effects on cognitive function and identifying pharmacological treatments for the reversal of age-related decline.

## Introduction

Reproduction can be an energetically expensive, complex, and risky phase within a female's life history cycle (Hazlerigg and Simonneaux 2015). To assist during these demanding periods, the adult female reproductive system has evolved numerous mechanisms to enhance reproductive success (Weems et al. 2015). One such mechanism in female mammals, excluding the old world monkeys, great apes, and humans, is estrus. Estrus is defined as “the periodic state of excitement in the female of most mammals that immediately precedes ovulation and during which the female is most receptive to mating; heat” (The American Heritage Stedman's Medical Dictionary 2004) and includes a number of endo- and exogenous factors, as well as behavioral components. The occurrence of estrus can be divided into three categories: polyestrous, seasonal polyestrous, and monoestrous. Polyestrous species have a succession of estrous periods throughout a single sexual season, while seasonal polyestrous species display estrous events in “clusters” during a specific period within a sexual season (Fig. 1).

**Estrous, Fig. 1** The graphical representation of seasonal polyestrous, polyestrous, and monoestrous

Finally, monoestrous refers to a single estrus event during a sexual season (Vasanthi 2016). During each estrus event, a number of fixed parameters are observed: the activation of the **central nervous system** (CNS) by environmental and endogenous cues, the resulting stimulation of the **hypothalamic-pituitary-gonadal** (HPG) axis and its regulation of estrus, the activation of estrus behaviors to assist in reproductive activity, and finally, the termination of the estrus event.

### External and Internal Cues Which Activate the Estrous Cycle

Ovulation, i.e., the release of an egg from the ovary, and the mating event required to ensure conception, are important components of estrus. However, as both components are energetically costly and time consuming, females aim to partake in this only if environmental conditions, and social dynamics, allow for successful mating,

conception, and pregnancy (Hazlerigg and Simonneaux 2015). As a result of this, ovulation in mammals has evolved into two distinct patterns, namely spontaneous and induced ovulation.

**Spontaneous ovulators** are known to display a constant cycle of reproductive hormones (e.g., polyestrous, Fig. 1), behavioral estrus and ovulation, irrespective of the presence of physical stimuli by a male (van Sandwyk and Bennett 2005). To ensure that the most favorable conditions are present when raising young, spontaneously ovulating females display a strong coupling of mating activity and date of parturition (Larivière and Ferguson 2003). Chemical, visual, photic, thermal, and/or tactile cues have all been shown to trigger reproductive activity in females, indicating the ideal time for mating and conception, and thus ensuring that young are born during favorable periods (Goldman 1999). For example, the use of photic cues (photoperiodism) allow an organism to use the annual progression of day length as a cue for determining the precise time of year and, thus, successfully regulate an individual's biological rhythm (Goldman 1999).

Another external cue involves the availability of food sources to initiate mating activity. In the natural environment, food resources are often limited or seasonally fluctuating, and as such, play an important role in regulating an organism's ability to reproduce successfully (Bronson 2009). To cope with this, organisms have evolved a number of strategies to ensure optimal energy acquisition and allocation to enhance reproduction. One such strategy involves capital and income breeders; **capital breeders** are species that build up energy reserves during periods of resource abundance but only reproduce at a later stage of the season. In contrast, **income breeders** allocate available resources directly to reproduction (Jönsson 1997). Nonseasonal regions, where resource availability remains constant, are advantageous to income breeders, as postponing reproductive activity does not lead to better environmental conditions.

In animal species where environmental cues are not a primary determining factor in driving mating activity, social cues may be a primary driver of reproductive activity. In contrast to

spontaneous ovulators, **induced ovulators** do not ovulate spontaneously and require direct copulatory stimulation to induce ovulation (Clemens and Weaver 1985). Here, the presence of a male acts as a cue for a female to initiate behavioral, physical, and physiological aspects of estrus. This mechanism allows females of solitary species, where male–female interactions are limited, to conserve energy, only investing in reproduction when a viable mate is in close proximity (Larivière and Ferguson 2003). Despite the different mechanisms driving ovulation in spontaneous and induced ovulators, similar pathways, in terms of the CNS and HPG axis, are present.

### The Neuroendocrine Control of the Estrous Cycle

Hormones are defined as chemical messengers that are excreted by an endocrine gland into the bloodstream, ultimately reaching a target cell and exerting a physiological regulatory action

(Woolley and Schwartzkroin 1998). The most well-known hormones include those that are produced and secreted by the thyroid, adrenal gland, and ovaries/testes. Of these, the reproductive hormones have been shown to underlie and regulate reproduction, forming an important part of the female estrus cycle (Wielebnowski and Watters 2007). The estrous cycle represents the cyclic patterns of ovarian hormone secretion (Fig. 2) and facilitates the transition of a female from a nonreproductive to a reproductive state (estrus), allowing for successful mating and conception (Forde et al. 2011). However, in order for the HPG axis to secrete the necessary reproductive hormones, along with their behavioral components, the initial activation of the CNS, through the applicable external and endogenous cues, is required. In **spontaneous ovulators**, factors such as photoperiodism act as a cue for CNS activation. In this regard, the photic stimuli is sent to the reproductive neuroendocrine system via the neurohormonal pathway, starting with the retinal projection (photoreceptors). From here, the stimuli is

main periods, namely follicular and luteal phase. Within the follicular phase, both proestrus and estrus are observed, while metestrus and diestrus are found during the luteal phase of the estrous cycle. The ovulation event is indicated

sent to the suprachiasmatic nucleus and finally through a multisynaptic circuit which is composed of neurons found in the paraventricular nucleus, intermediolateral spinal cord, and superior cervical ganglion, before reaching the pineal gland (Weems et al. 2015). The resulting production of melatonin by the pineal gland plays an important role in conveying specific photoperiod information to the hypothalamus and other regions of the brain. In **induced ovulators**, the activation of the CNS is controlled by the receipt of genital somasensory stimuli (Bakker and Baum 2000). In both spontaneous and induced ovulators, the stimuli from the CNS activates the HPG axis, resulting in the secretion of a number of reproductive steroid hormones such as gonadotrophin-releasing hormones (GnRH), luteinizing hormones (LH), and follicle-stimulating hormone (FSH), as well as estrogen and progesterone (Fig. 2; Vasantha 2016).

### Phases of Estrus

The estrus cycle can be divided into the follicular and luteal phases, both of which have a number of specific substages defined as proestrus, estrus, metestrus/diestrus, and anestrus (Fig. 2).

#### Proestrus

Following the activation of the CNS by the specific environmental or endogenous cue, the hypothalamus secretes GnRH in pulsating bouts, which is transported to the pituitary gland (Christensen et al. 2012). In order for GnRH to apply both trophic and regulatory effects on the HPG axis, it interacts with the G-protein-coupled GnRH-receptors located in the pituitary gland, forming a hormone-receptor complex (Naor 2009). **Hormone receptors** are molecules found in target tissues which interact with hormones, altering the biological activity of the receptor, and ultimately changing gene expression and cellular activity (Pfaus et al. 2015; Sinchak and Wagner 2012). This binding event results in the production and secretion of the glycoprotein hormones, LH and FSH. Both LH and FSH stimulate and enhance ovarian follicle maturation and development, as part of the follicle phase (Fig. 2). Furthermore, LH and FSH bind to their

**Estrous, Fig. 3** A representation of the hypothalamic-pituitary-gonadal axis in female mammals. Hormonal production, secretion, and paths are indicated by solid arrows. The positive and negative feedback loops are indicated by dashed lines

respective G-protein-coupled hormone receptors found on the thecal and granulosa cells of the ovary (Hillier 1994). This binding results in the production and secretion of cholesterol derived androgens, which in turn are aromatized by the granulosa cells to produce estrogen and progesterone (Fig. 3). As a result of the high lipophilic nature of both ovarian hormones, they are able to easily cross the blood-brain barrier and diffuse through cell membranes, ultimately altering cell activity (Woolley and Schwartzkroin 1998). The increase in estrogen concentration during this period results in the activation of a positive feedback loop between estrogen, the brain, and the pituitary gland (Fig. 3). This positive feedback loop promotes an increase in GnRH, and its

receptors in the pituitary gland, which enhances pituitary responsiveness to GnRH, and leads to a LH secretion surge (McCarthy and Becker 2002). The LH surge, along with FSH secretion, plays an important role, during the ovulatory phase, to ensure follicle maturation, ovulation, and a further increase in estrogen secretion (Hillier 1994). The increase in concentration of the respective hormones described (GnRH, LH, FSH, estrogen), along with **reproductive behaviors (attractivity, proceptivity)**, form an important component of the **proestrus** period in females (McCarthy and Becker 2002).

#### Estrous

The continuous increase of circulating estrogen and progesterone has two important functions. Firstly, the sequential increase of estrogen, along with secreted progesterone, act upon reproductive tracts to prepare the uterine endometrium for copulation and embryo implantation (Sinchak and Wagner 2012). Secondly, circulating estrogen, and to a lesser degree progesterone, bind to receptors within the brain and are vital to the initiation of sexual activity during the estrus cycle (Pfaus et al. 2015). Although an estrogen-only steroid regime is capable of activating reproductive behaviors, a delay in activation is seen herein compared to an estrogen-progesterone steroid regime (Sinchak and Wagner 2012). Although mostly facilitative in nature, progesterone can also inhibit reproductive activity in certain species (Lipschitz 1997). As different steroid regimes are capable of activating, or inhibiting, reproductive behaviors, it is clear that multiple neural pathways may mediate similar behaviors. Of great physiological importance is the synchronization of the estrogenic increase of GnRH and LH, along with the ovulation event, to the activation of reproductive behaviors allowing for successful conception during estrus. Receptive behaviors are limited to the estrus period during the estrus cycle.

#### Metestrus and Diestrus

Following the ovulation event, LH causes the terminal differentiation of the ovulated follicle into the corpus luteum (CL) through the process
